When selection pressures on a character are strong, the gene for that character that has the greatest survival value will be selected. This means that genetic variation is reduced, as the poorer-performing genes are selected out and only the optimum genes remain in the population. Thus, beef cattle have the best available genes for pre-weaning survival, and there is almost no genetic variation for this character, indicated by low values for heritability. The situation is different in wool sheep - although it is usually a commercial advantage to have a heavy fleece, it would make survival different under certain circumstances. So, genes for heavy fleece weight will sometimes be advantageous and at other times a disadvantage - and the genetic variation that exists for this character reflects the overall balance of advantage and disadvantage. It would not really be practicable to attempt selective breeding for a character that has a low heritability, as there is only a small amount of genetic variation to work with.

Heritability can be measured by calculating the correlation between the values parents have for a character and the values for their offspring, because this measures the importance of genes in determining the latter. Generally, rather few measures have been made of traits relevant to welfare. Certain aspects of the docility of Limousin cattle have a heritability of about 22%, and this is enough for a breeding programme to be justified with a view to improving their temperament. **Tonic immobility (TI)** in chickens, which is thought to reflect **fear**, is highly heritable. However, selection for a short duration of

TI would not necessarily improve welfare, because the resulting animals might be just as afraid but less able to express their fear behaviourally through tonic immobility.

Heterochrony

Heterochrony refers to phylogenetic changes in the relative timing or rate of developmental processes between individuals (**see also: Development - behavioural**). Two forms of heterochrony are recognized: (i) paedomorphosis, in which juvenile characteristics are retained into adulthood (i.e. certain developmental traits are lost or delayed); and (ii) peramorphosis, in which additional development occurs during the ontogeny of an individual. The exaggeration of certain traits as might occur as a result of **sexual selection**, such as the extensive antlers of some species of deer, is an example of peramorphic change.

Many species - and especially domestic variants - appear to show a mix of paedomorphic and peramorphic change. For example, some giant **dog** breeds such as the St Bernard appear to have many paedomorphic characteristics (a more domed skull and shortened muzzle more typical of the ancestral neonate, as well as a more juvenile behavioural repertoire), but their large size may be explained, at least theoretically, in terms of either a paedomorphic or peramorphic process or a combination of these. This is possible because there is a range of processes that can give rise to heterochrony that are neither exclusive nor necessarily easy to distinguish.

Table H.1. Types of change in development seen as a result of different heterochronic mechanisms.

Developmental feature changed	Heterochronic change	
	Paedomorphosis	Peramorphosis
Offset time	Earlier - progenesis	Later - hypermorphosis
Onset time	Later - post-displacement	Earlier - predisplacement

Rate	Slower - neoteny	Faster - acceleration

In the example above, it might be argued that a delay in the onset of maturity (post-displacement) - and the associated slower adult growth pattern as a consequence - results in a prolonged period of accelerated growth typical of a juvenile (a paedomorphic trait). However, it might also be argued that it is primarily a delay in the ending of the juvenile phase of development (hypermorphosis) that results in an extended period of increased growth (a peramorphic trait). While the later than average age of sexual maturity of this breed might be viewed by some as tending to favour the paedomorphic explanation, it should be noted that this breed still matures much earlier than its wolf ancestor, which might suggest that more extensive developmental recombination has occurred during the development of the breed, resulting in a mixture of paedomorphosis and peramorphosis both within and between different traits. Sweeping generalizations concerning the heterochronic changes associated with **domestication** and breed diversification are therefore best avoided.

There are three basic mechanisms that might result in each form of heterochrony: (i) a change in the offset timing (ending) of development; (ii) a change in the onset timing (start) of development; and (iii) a change in the rate of development. The consequences of each are given in Table H.1.

While simple generalizations about paedomorphosis and peramorphosis can lead to false conclusions, it is reasonable to suggest that different environmental circumstances tend to favour the occurrence of different heterochronic processes; for example, in stable environments (in which k-selected species will tend to flourish), there are often advantages associated with having a prolonged developmental period (i.e. hypermorphosis and neoteny are more likely to occur) in order to facilitate greater competitive ability as an adult, such as through the increased experience gained from **play**, **exploratory behaviour** and possibly opportunities for **social learning**. Conversely, in less stable environments (which tend to favour r-selected species), more rapid development (acceleration) with an earlier completion (progenesis) may be favoured in order to maximize reproductive potential by minimizing generation time.

Hiders

Among the **precocial** ungulate species, those in which the young remain concealed near the birth site for some time following parturition (usually several days), while the mother can be away for long periods of time, are designated hiders. The young of those species avoid predators largely through **cryptis**. Hiders are generally considered to be the opposite of the **followers**. However, the distinction between those two

categories of species might not be so rigid, as some studies suggest that the response pattern of the young within a species may be flexible depending on ecological factors.

(SL)

Hierarchy

When animals come together in a **group**, generally in order to cohabit, they establish social relationships between group members (**see: Social behaviour**), and one outcome of these relationships is the establishment of a so-called **dominance** hierarchy or social hierarchy. The term 'hierarchy' suggests that the animals are arranged in some kind of static graded or ranked order, but in most animal groups this is an oversimplification, as relationships between individuals are often dynamic and situation-specific and may involve coalitions formed with other group members.

In 1922 Schjelderup-Ebbe, studying the social organization of flocks of domestic hens, used overt **aggression** (pecking each other) as a measure of dominance and described a 'peck order' (hierarchy) among the birds. The simplest form of hierarchy is one in which one individual dominates all other group members, with no rank distinctions among the subordinates; this is a 'despotic' hierarchy. More commonly, hierarchies have multiple ranks in which individual A dominates all others, individual B dominates all but A, individual C dominates all but B and A, and so on down to the most subordinate individual that dominates no other; such a hierarchy is termed a 'linear' hierarchy. Many hierarchies are more complex, and contain animals of equal status, triangles or other circular elements - e.g. B may dominate C, which dominates D and E, which are of equal status and both dominate A. The hierarchical relationships are said to be established and stable if the pattern of the previous outcomes allows an accurate prediction of the next outcome.

The form of the hierarchy may be dependent upon the way in which the hierarchy develops, and the method of development appears to differ with species, depending upon the factors that influence the dominance potential in a particular species, and also whether relationships are established instantaneously or develop over time. For cattle, length of time in the herd appears to be a crucial contributor to dominance. Thus, if new members are added to a group in succession, then the hierarchy is more likely to approximate linearity than if several new members are added at the same time.

The function of the hierarchy is debatable, although its role in reducing aggression receives much support. This reduction in aggression appears to arise from individuals being able to assess the dominance potential of others by individual recognition, the recognition of attributes or cues associated with those attributes, and during encounters. The dominant animal may assert its dominance through aggression most frequently and vigorously when the relationship with another is least stable, such as when the relationship is newly established or has recently been reversed. This suggests an inverse relationship between frequency and intensity of aggression and the degree to which relationships are established and stable. The mixing of unfamiliar animals is reported to invariably result in an increase in levels of **agonistic behaviour** interactions. This indicates that at least some group members need to interact to physically determine social relationships and do not rely on cues and traits that are indicative of dominance. Evidently, situations such as mixing unfamiliar animals that result in high levels of aggression can cause excessive physical exertion, exhaustion and **injury**, and adversely affect welfare.

The social hierarchy is often regarded as having an allpervasive influence on the life of animals, governing not only social and aggressive interactions but also influencing access to all resources. Thus, the hierarchy is seen as determining: when and where individuals move and rest; where, when and what they eat; with whom mating occurs and how successfully they reproduce. If this is the case, then there are obvious consequences for the **welfare** of group members depending upon their position within the social hierarchy. If dominant individuals have to be extra-vigilant, and spend time and energy frequently defending resources and their position in the hierarchy, then their welfare may be poor. In the case of

species in the care of humans, some of the effects on welfare may be attenuated because resources may never be limited to the extent that particular individuals are totally deprived. However, the welfare of some individuals could be compromised because the resources they obtain may be of inferior quality; for example, there are reports that individuals at the bottom of the hierarchy access poor-quality food.

It is reported that large groupings of livestock animals can lead to poor welfare in certain individuals, because high levels of aggression arise as a result of difficulties in establishing a stable hierarchy with large numbers of individuals. If correct, this explanation implies that individual **recognition** is used in the development and maintenance of the hierarchy, and aggression occurs because it is difficult for individual recognition to occur in very large groups. In contrast, if hierarchies were to be established and maintained by individuals **learning** that certain traits or cues are associated with dominance, then after a few initial encounters individuals would recognize the cues and know the social relationship without further aggressive encounters occurring.

It is often noted that there are more aggressive interactions among individuals in the middle of the hierarchy than among those at the top. This is probably a consequence of the disparity in attributes that contribute to dominance potential being less clear-cut among the middle-ranking individuals. Individuals at the bottom of the hierarchy are often reported as having considerable aggression directed towards them, and may be constantly 'bullied' or harassed. Such harassment is more likely to occur when space is restricted and the subordinate individual is forced into close proximity to others, or is unable to escape from and/or show unambiguous submissive behaviours to individuals dominant to it. There would be obvious adverse welfare consequences for such subordinate animals: they risk

P.316

injury, may have limited access to resources or access only to resources of poor quality, and may experience severe **stress** resulting from social tension (see: **Social stress**). (JCP)

Hill sheep

Hill sheep are hardy animals that have usually been developed to survive the tough conditions found on uplands and mountains. They do not merely survive but are productive on the poor-quality **grazing** typically found in these areas. Typically they have a thick fleece, which helps them deal with the cold and exposure they face, especially at lambing time. Hill breeds of **sheep** characteristically have a good mothering ability, give lots of milk and keep a careful watch on their offspring. Indeed, ewes become particularly disturbed if their lambs are taken away from them and will often jump out of a pen in order to search for them. Many breeds have a relatively small head, which means lambing is easier and needs minimal assistance.

Although the fleece is thick, in many breeds it has a high content of coarse and black fibres, which decreases its quality and thus its value. However, traditional carpet manufacture has utilized this hard-wearing wool, and centres of carpet manufacture are often found close to upland areas.

Hill sheep breeds tend to be smaller in stature than lowland breeds: a Welsh Mountain ewe weighs only approximately 45 kg. The conformation of the animal is often poor, especially the rear quarters, which show little or no rounded muscling. Combined with the lighter weights, this means prices paid for carcasses of hill sheep breeds are significantly lower than for those from lowland breeds. Hill sheep

brought on to improved pasture or given supplementary feed for finishing can easily become over-fat, as they put on a greater proportion of fat to lean muscle compared with lowland breeds.

Hill sheep breeds are strongly associated with the areas from which they originate, and have typically been refined to suit the conditions found there. Examples from the British Isles include Welsh Mountain, Scottish Blackface, Swaledale, Lonk, Herdwick and Loaghtan. The Charmoise breed, imported from France, is also sometimes found on farms with slightly more favourable conditions, as it has better conformation than many British breeds.

Hinduism

The origin of Hinduism is in the multitude of different belief systems with roots dating back to 3000 BC around the valley of the Indus in India. There have always been, and still are, a multitude of Hindu belief systems, but in 1966 India's highest court stated some common core elements: tolerance of different life views; a cyclical world course; reincarnation; and Vedic (the precursor to Hinduism) scriptures being regarded as central. Originally in Vedic times, animal sacrifice was common. In the *Ishopanishad* (scripture), the spiritual way to salvation is stressed, which, in combination with the aim of escaping rebirth through good *karma* (effect of deeds), often leads to a more humble relation to other life forms.

Thanks to influences from **Buddhism** and **Jainism**, the ideal of *ahimsa*, non-violence, became influential in Hinduism. **Vegetarianism** is regarded as a practical conclusion of these elements and is usually highly regarded, or an ideal for many people.

A great advocate for non-violence and practising vegetarian was Mahatma K. Gandhi (1869-1948). According to him, strict vegetarianism 'is for building of the spirit and not of the body. Man is more than meat. It is the spirit in man for which we are concerned' (Gandhi, 2002 (1959)). In fact, Gandhi's moral standpoint was what we would call veganism today. He also regarded it morally wrong to use milk products because they, like meat, 'bring with them the defects of the animal from which they are derived' (Gandhi, 2002 (1959)). Thus Gandhi argued for care for sentient animals with the focus on human spiritual salvation, i.e. striving towards relief from rebirth through reverence for life. However, some Hindu teaching not only accepts but also prescribes meat eating, and in fact only a small proportion of Hindus are vegetarian. This is due to both different interpretations of the principle of *ahimsa* and a gap between religious ideology and practice. The difficulty in translating ideology to practice becomes explicit when thinking of the cow. She is regarded as sacred, but often suffers from **hunger**, **stress** or **injury**. This is due not only to an interpretation of sacred as prohibiting the killing of cows, but there is also large-scale industrial milk and meat production in India.

Homeostasis

A fundamental characteristic of living organisms and open systems, homeostasis is the property to regulate the internal environment and to maintain its stability through dynamic adjustments. An example of homeostasis is the capacity of endothermic animals to maintain a stable body temperature despite what happens in the external environment. Planet Earth is another example of a homeostatic system.

Home range

The concept of a home range seems implicitly understood, but is difficult to define and measure precisely. It is often defined as the area that an animal routinely uses. Alternatively, the home range may be defined as the area that an animal is familiar with (which would be larger than the area that it normally uses) or the area that it uses a large proportion of the time (hence excluding areas used only occasionally).

Most animals do indeed have home ranges - they do not wander aimlessly across the landscape. It was once thought that species like polar bears and African wild dogs did not

P.317

restrict their movements to a defined range, but it was later learned that they just have very large ranges.

Why do animals have home ranges? Familiarity with an area enables animals to better utilize the resources. It is believed that many, maybe most, animals have a sort of **cognitive map**, enabling them to return to good feeding spots, water holes, shaded rest areas and places that offer safety from predators or shelter from storms. If they did not reuse areas and gain familiarity with the distribution of resources, they would be less efficient in obtaining these resources and also subject to greater risks. The trade-off, though, is that by remaining in one area they may deplete their resources. Moreover, resource availability may change radically from season to season or year to year, prompting some animals to shift their home range or make seasonal excursions or migrations. If an animal consistently migrates to the same area, that too should be considered part of its home range. But if it makes occasional sallies to new areas on occasion, our perception of its home range becomes more muddled.

To an individual animal, the distinction between what is within versus outside its home range is probably not black and white, unless it is strictly territorial. A **territory** is a home range (or part thereof) exclusively used by an individual or group, often abutting another distinct area used by another individual or group. The borders may be marked by scent, sign or a worn pathway from frequent patrols. Non-

territorial home range boundaries are far more vague. Thus, human observers often have a hard time discerning the boundaries and measuring the area.

Researchers studying home ranges usually obtain a series of point locations, either from visual observations of recognizable individuals or, more commonly, from individuals that are tracked by radio telemetry over some period of time (a year or more, if the intention is to estimate an annual home range). Home range is then often delineated as the area enclosed by connection of the outermost points. In the early days of development of this technique, it was quickly recognized that different observers perceived the outermost points differently. To standardize the process, a definition was imposed that all outside angles formed by the perimeter must be convex hence yielding what is called a minimum convex polygon (MCP).

While simple and intuitively appealing, the MCP technique has problems: namely, the encompassed area may include places that the animal never (or very infrequently) uses. Imagine that an animal uses areas on both sides of a large swamp, but not the swamp itself. Its MCP range would nevertheless include the swamp. Such areas of non-habitat can be excised from the calculated area if they are obvious and well delimited (lakes, glaciers, agricultural fields, towns, etc.). But, in most cases, there is a gradient among habitats in their degree of use. Suppose open grasslands are traversed only at night, to get from one forest patch to another; should they be excised out or be included in the home range?

This dilemma led researchers to develop methods that considered the *amount* of use in various portions of the utilized area (the so-called **utilization distribution**, or UD). Graphically the UD is portrayed not as dots on a map, but rather as bars of varying heights representing the number of times, or amount of time, that each spot was visited. Mathematical procedures can then be applied to assess the area of use from the UD. The result depends on the procedure chosen (there are at least half a dozen, with kernel estimators currently favoured) and on how well the data reflect the true home range and fit the assumptions specific to the procedure.

These UD-based procedures measure not the full area of use, but the area that the animal uses some proportion of the time (usually 90 or 95%); inner contours (isopleths) can be drawn to indicate increasing degrees (probabilities) of use. Travelways connecting commonly used areas are usually not included, due to their infrequent use, resulting in home ranges that often look like disjunct blobs rather than a contiguous area. This makes sense if the aim is to delineate areas of common usage, but is not very useful if the goal is to ascertain how large an area to protect (e.g. as a park or reserve) to contain the home ranges of a certain number of animals; in that case, the spatial separation of all the little home range blobs is also relevant. No currently developed procedure is available for doing this. In that regard, the traditional, albeit flawed, MCP has value in outlining the total physical area occupied, even if not all of it is used. In terms of ecological and behavioural questions, however, the UD is more instructive for assessing patterns of use within the home range, relative to food sources, habitats, **conspecifics**, competitors, predators or other threats.

Home range size is largely a function of the size of the animal, its sex, **social system** (including group size) and availability of food. Larger animals, being both more mobile and requiring more food, have larger home ranges. Males typically have larger home ranges than females, not only because they are larger, but because in many species males seek to breed with multiple females.

High food availability enables animals to persist on smaller home ranges. Thus, within taxa, home range size may be a metric of habitat quality; hence, home range size tends to increase with latitude. Even across taxa, home range size reflects biomass of available food: for example, giant pandas may have 100,000 times the biomass of food per unit area of a polar bear (the former subsisting on bamboo, the latter on seals); as a consequence, polar bears require areas at least 20,000 times larger. It follows that carnivores, in general, require larger home ranges than equal-sized herbivores.

However, like everything in ecology, these sorts of relationships have numerous confounding variables. High food availability supports high animal densities, either squeezing them into small home ranges or causing so much intraspecific overlap, and hence resource competition, that home ranges need to be bigger. It has been suggested that highly fluctuating food resources lead to expanded home ranges (in preparation for times of food failure) with more home range overlap (because in most years there is a surplus of food within each range).

Hominoidea

This super-family of species, the so-called 'great apes', comprising gorillas, chimpanzees and orang-utans, are the closest relatives of humans. They are the largest living primates, have no tail, they have a barrel-shaped chest and their forelimbs are longer than their hindlimbs, which are used to ambulate.

(DBM)

Homology

Two structures are homologous when they share the same phylogenetic origin regardless of their current function. An example of homology is the wings of bats and the forelimbs of terrestrial mammals, as these two structures evolved from the same ancestor, although they currently have differing functions.

(BM)

Homosexual behaviour

Homosexual behaviour describes within-sex **sexual behaviour**, although there is some disagreement over the sorts of behaviours that should be assigned to this. It is usually taken to include: **courtship behaviour**, mounting, genital contact, genital manipulation, pair bonding, affection and **parental behaviour**.

Historically there has been some recognition of this behaviour among animals, particularly among bird species. But homosexual behaviour in animals was perhaps most famously, and at the time shockingly, reported in the 1950s with fish (sticklebacks) and **rats** - the first probably as a result of a lack of females, the second thought to be the result of **stress** through overcrowding. Observations have, more recently, been reported in a wide range of species across classes, including birds, **reptiles**, **amphibians**, crustaceans, octopi, spiders and insects, as well as many mammalian species. It perhaps therefore should not be seen as abnormal, but as part of an animal's complex sexual repertoire.

This is a subject that is fraught with the possibility of bogus analogies with human behaviour and, perhaps as a result of this, there has been very little research in animals and it is little understood. Homosexual behaviour is more often observed in younger animals, by members of both sexes, within the context of **play**. Male homosexual behaviour has been identified with the expression of **aggression**, and it has been surmised that it is therefore more common in species with social hierarchies. In females a similar aetiology is proposed, and it is most often observed during, or around, **oestrus**. **Macaque** females have demonstrated kin avoidance in their homosexual partner selection. Recent work, including work on the guppy and primates, seems to indicate that the social environment is important, with manipulation of the sex ratios of captive groups varying the degree of expression of male-male homosexual behaviour. This has implications for the husbandry of captive animals, and particularly those kept for **captive breeding programmes** for **conservation** purposes, although engaging in homosexual behaviour does not necessarily preclude normal reproductive behaviour and outcomes with other mates.

It has been reported variously that expressions of this behaviour are more commonly seen in captivity than in the wild. On the other hand, there is contrary evidence, at least for primates, with observations of homosexual behaviour being more common in groups in free-range environments. Indeed, accurate judgements regarding the natural expression of this behaviour in the wild are likely to be compromised, as captive animals are observed more frequently and intensively than those in the wild. Homosexual behaviour shown by larger, more striking, animals also features in the scientific and lay literature more often than for other species, presumably because they are more obviously noticed than other animals.

Suggested mechanisms determining the expression of homosexual behaviour have included neural and hormonal factors, the latter either during the animal's lifetime, perhaps during puberty or while *in utero*. Rats subjected to prenatal maternal stress are reported to have expressed altered sexual behaviour in maturity, but the evidence is equivocal. There is evidence from a range of animal classes, including insects as well as vertebrates, that homosexual behaviour has a genetic basis. Evolutionary pressure in favour of the retention of this behaviour in a population would at first sight seem to be unlikely, as it is a sexual behaviour that can result in no offspring. However, it may be that, as a demonstration of social **dominance**, it might allow individuals to enhance their position in the dominance **hierarchy** and thus improve their successful choice of sexual partners. Among females, mounters rather than mountees have been found to be the dominant individuals in the main. It has been speculated that repeated mounting of co-females may reduce the frequency of their solicitations to males, thus leaving the field freer for the dominant mounters. There might be a further evolutionary advantage to the group rather than to the individual, by promotion of social cohesion and the support and protection this provides. The individual may not pass on their own genes, but by sacrificing themselves to the nurture of close kin, they will improve the possibility of some of their genetic endowment being passed on to the subsequent generation.

The act of engaging in homosexual behaviour may help group cohesion too; bonobos (*Pan paniscus*) have been observed exhibiting homosexual behaviour after periods of aggression in the group, which seems to help in defusing the conflict. It should also be noted that among animals homosexual behaviour is most often not an exclusive contact; female individuals may show homosexual behaviour, yet also mate successfully with males, allowing any genetic component to be retained in the population. Indeed, practising homosexual behaviour may maintain reproductive readiness for whenever a suitable mate should become available.

Domesticated animals are thought to engage in homosexual behaviour more often than wild animals, though there are exceptions. It has been said that the normal social construction of mountain **goats** and **sheep** is basically homosexual, with

P.319

dominant males treating, and responding to, subordinate males and oestrous females in the same way. It is believed that domesticated animals may have been selectively bred to perform homosexual behaviours. Those obviously showing sexual behaviours might have been more easily observed and selected for mating. Current methods of oestrus detection and semen collection of some species of domestic animals could scarcely function without the ready expression of this behaviour. For example, most methods of oestrus detection of dairy cows rely on detecting female-on-female mounting behaviour (see Fig. H.2), while semen collection relies on the ready mounting of bullocks by the donating bull.

Fig. H.2. Homosexual behaviour: a dairy cow being mounted by another.

From an animal welfare science perspective, incidents of homosexual behaviour have been suggested as indicators of stress. However, reports of homosexual behaviour as an **abnormal** behaviour and therefore an indicator of stress must, in the light of the above, be questioned, unless other evidence is provided. Until more is known regarding the mechanisms and norms of this behaviour for each species, with respect to age, stage of sexual cycle, social dominance, social structure, presence of other-sex individuals and degree of **domestication**, conclusions from observations of homosexual behaviour in animals and their welfare should be treated with caution.

Honest signals

Signals are the means by which animals communicate with each other. However, defining **signals** and **communication** within a framework of animal behaviour is fraught with difficulties. Animal signals are unlikely to be 100% honest 100% of the time. When the interests of the signaller and receiver are the same, signals tend to be sufficiently conspicuous to be detected, but remain largely unexaggerated. An **analogy** might be the brake lights on the back of a car - it is mutually beneficial for the driver that is braking (the signaller) to signal to the driver behind (the receiver) that he/she is stopping; thus both parties avoid a costly accident. In this case the signal is honest as there is no benefit to the signaller in giving out false information about the intention to stop.

However, in some cases, the interests of the signaller and receiver do not coincide. When this occurs, signallers (and thus signals) can manipulate the response of receivers. For example, consider two dogs in conflict over a piece of food. The weaker dog that gives a threat display that results in the stronger rival backing down would have successfully manipulated it. Thus there is selection on the threat display to become more exaggerated. However, there is now selection on the receiver not to be manipulated by exaggerated signals (i.e. to detect and respond to true information conveyed by the signaller). Thus the co-evolution of manipulation and countermanipulation may ensue, potentially resulting in exaggerated signals (the song of the nightingale or the feathers of a peacock) that essentially convey honest information about the qualities of the signaller. These exaggerations may further ensure a degree of honesty, as only individuals in good condition can afford the cost of producing such elaborate displays. There are also clear cases of dishonest signals - e.g. Batesian mimics signal that they are poisonous or dangerous by exploiting conventional signals used by other species, yet carry no such defences against predators.

Horse

Most equidae are plains feeders. They generally do not defend territories in the wild but rather occupy **home ranges** and prioritize membership of a cohesive **social group**. Like other social herbivores, they capitalize on **conspecific** companionship for added safety, mutual comfort and enhanced detection of food. Apart from dispersal as juveniles, they avoid becoming isolated. With long noses that allow them to graze while maintaining surveillance above the sward, horses rely largely on caution, speed and agility as their chief means of selfpreservation. Contrary to some reports, they do not have a ramped retina but accommodate using ciliary muscles in the same way as most other mammals.

Horses have a large caecum, and so are able to digest material that ruminants generally overlook. Carrying such a voluminous fermentation vat obliges them to have tremendous muscular power to shift their considerable bulk from rest to top speed at times of danger. The same muscles that propel horses from danger provide power to their hindlegs, which can be extended explosively to kick with tremendous accuracy and effect. Because of its small stomach, the horse is a so-called 'trickle feeder' and must forage frequently rather than eating and then ruminating, so periods of fasting are more profound insults to equidae than to members of many other herbivore species.

P.320

Unfortunately, **housing** and stable management rarely take full account of the horse's need to socialize and to forage frequently. Accommodation generally imposes confinement and social limitations on them, while feeding regimens often constitute radical shifts from the horse's natural **time budgets**. These departures are critical in the **ontogeny** of common unwelcome behaviours in intensively managed horses. For example, social isolation has been identified as an important factor in the emergence of **weaving**, while discrete meals that allow gastric acidity to build up have been implicated in the development of **crib-biting** (and **wind-sucking**).

Horses have almost 350° vision, but their caudal blind spot accounts for some of their tendency to startle readily when stimuli appear from the rear. With dichromatic colour vision, they can be likened to colour-blind humans who see pale blues and yellows but cannot easily distinguish these from reds. Although their sense of taste is used to discriminate between safe and toxic plants, its accuracy is variable. Horses have highly developed accessory **olfaction** and an ability to hear within and beyond the range of human hearing. From a rider's perspective it is important to note that horses have predictable zones of very sensitive cutaneous sensation.

Because riders provide horses with cues in the form of pressure (e.g. from their legs to the horse's sides) and remove the pressure when the horses have made the desired response, equitation relies on negative reinforcement. However, successful innovations that accentuate the positive are being developed. For example, **clicker training** offers a simple method for shaping appropriate responses and therefore provides a basic framework for retraining many unwelcome responses, especially in the unriden horse. Horses are remarkably adaptable and tolerant, and their ability to learn facilitates their behavioural flexibility in novel environments. That said, it does not appear easy for horses to copy novel behaviour patterns, which suggests that imitation of **stereotypies** is unlikely. Although **habituation** is the pivotal technique for overcoming flight responses, most horse **training** involves **operant** conditioning and shaping that relies on reserving reinforcement until an improved response appears. Consistency and timing are the hallmarks of good training and are prerequisites if classically conditioned cues are ever to replace operant relationships.

In the free-ranging state, horses form social hierarchies that are complex and rarely linear. They seldom have the equivalent of an alpha individual, because the social roles of leadership and defence are more critical than that of simple domination. Social hierarchies determine the order in which members of a group access resources, but also increase stability in the band and decrease **aggression, injury and distress**. Social rank is not determined by weight, height or sex so much as by age and length of residency in the group. In addition, **matrilineal** dynasties can be observed in many bands of horses, while the rank of stallions is very much context-dependent.

Individual attachment, most notably in the form of pair bonds, is the fabric of social groups. While stallions tend to form weaker pair bonds than mares, juveniles or bachelors, this does not justify isolating them from conspecifics within domestic contexts. Domesticated horses have similar social organization to their free-ranging counterparts but often show more aggression because of various impositions, including **social flux**. Housed horses benefit from appropriate social contact with **conspecifics**.

Because horses have excellent vision, communication among them can involve very subtle body language. Ear position and head posture seem to be the most important variables in non-vocal communication between individuals, while the position of the tail can help to coordinate the movements of a group. To signal their readiness to mate, mares use olfactory cues in urine and visual cues (e.g. the characteristic posture of an oestrous mare during urination). Stallions avoid aggressive interactions by means of dung piles and the rituals attached to them.

The importance of strength and athleticism in horses for those who work with them and use them in competition means that locomotory health is often of prime concern. Movements *in utero* are of tremendous significance in priming a foal for **precocial** existence, and it seems that all horses have a **behavioural need** to stretch and locomote. **Gaits** have evolved for economical energy use at any given speed, and it is clear that whips, conditioning and warming up can influence **locomotion** in ridden horses. Kinematic studies are useful for studying **lameness** and the within-gait differences required in dressage, but there is room for considerably more scientific investigation of the cause-and-effect relationships between riders and horses, especially since the prevalence of wastage for behavioural reasons is unacceptably high.

In the free-ranging state, horses may graze and forage for up to 19 h a day. Food selection allows them to adjust their intake of nutrients to suit their current situation, and indulge their innate dietary preferences for sweet-tasting foods and short, young grasses high in fibre and carbohydrate, while avoiding poisonous alternatives. There is also individual variation in **preferences** and **aversions**, and horses may learn which foods to select from both conspecifics and personal experience.

Concentrated feeds encountered in domestic settings are associated with reduced saliva production and increased gastric acidity. In addition, periods without food precipitate yet more gastric acidity and the risk of gastric ulceration. This is compounded by a lack of forage that, in cross-sectional epidemiological studies, has been identified as the most important management factor linked to the development of stereotypic behaviours. Crib-biting and wind-sucking have also been associated with concurrent disorders of the digestive system (e.g. there is a significant association between stomach ulceration and crib-biting in foals). Therefore, treatments and management styles that reduce the incidence and severity of oral stereotypies by normalizing ingestive behaviour offer humane avenues for the improvement of the welfare of all stabled horses.

Grazing behaviour at pasture can be affected by the distribution of faeces and urine. Faecal material makes the grass less appealing, even though the grass itself is readily consumed if presented to horses without contamination. This prompts the development of latrine areas and so-called lawns, the main body of the pasture that, as a result, carries fewer **parasites**. Urination and defecation are profoundly

influenced by age and sociosexual factors. For example, breeding stallions may use urine to mask olfactory stimuli left by other horses.

Self-grooming can take many forms, including rolling, shaking, rubbing, scratching, nibbling and licking.

Body care also

P.321

involves movements that facilitate pest avoidance and behavioural **thermoregulation**. Humans often spend a great deal of time **grooming** their horses and tending to their cosmetic appearance. While usually well intentioned, this can occasionally be inappropriate and even abusive. Inappropriate grooming includes excessive removal of sebum - which denies horses some of their natural weatherproofing - and brushing and pulling hairs to the extent that the horse is irritated and the horse-human bond is compromised. The removal of vibrissae at the end of the nose is inappropriate, as these are thought to be the chief means by which horses feel objects that are out of their line of vision. On the other hand, mutual grooming is of tremendous importance to horses because it affirms social bonds and, by lowering heart rates, is thought to have a role in stress reduction. So, grooming by humans can even affirm the bond between horses and their human carers.

Using a specialized apparatus in their lower limbs that relies on a system of reciprocal tension, equidae can rest with minimal muscular exertion. This conserves energy and allows them to rest while standing, thus reducing the need to enter sternal or lateral recumbency. In domestic contexts, the quantity and quality of **sleep** can be influenced by age, rank, group size, diet and environmental stimuli, including housing.

Stabling can compromise a horse's ability to safely perform many normal maintenance responses, such as rolling. It also affects the horse's ability to undertake locomotory and interactive **play**, behaviours that are recognized as being important for physical and psychological well-being. Play among foals and between foals and adult horses also has a significant role in the development of social behaviour, including learned inhibition of agonistic responses. Prior to 1 month of age, play is more likely to be solitary or with the mother, whereas after 1 month of age play is more likely to be with peers.

The behaviour of stallions has been broadly misrepresented in popular culture as being focused on domination rather than on benign harem maintenance, and this may have given rise to the notion that they are predominantly aggressive animals. In fact, the leadership role of stallions within a family band is largely confined to keeping foals safe from predators and mares away from other stallions. In the free-ranging state, a harem stallion interacts with his mares almost continuously and so can avoid errors in the timing of copulation. Free-ranging matings are generally more productive than those orchestrated by human managers, who seek to use courtship primarily in teasing and the development of an erection, and limit the number of copulations per stallion in a putative bid to maintain sperm reserves. Because of the poor timing of managed matings and the fact that they are not fully receptive, mares are regularly restrained during service so that they cannot harm the stallion if they attempt to kick.

Seasonality has little effect on a stallion's **libido**, and this has allowed the emergence of so-called shuttle stallions that travel between the northern and southern hemispheres serving mares throughout the year. Factors that do affect the sexual responses of stallions include individual preferences, visual stimuli, olfactory stimuli and learning. The latter includes learning to avoid mating because of discomfort associated with peri-coital stimuli, including forced dismounts, unreceptive mares and penile and musculoskeletal lesions. It is now accepted that stallions can be allowed to mount without an erection and that, if it becomes necessary to force a stallion to dismount, this should be accomplished without aversive stimuli that can have unpleasant associations later. Allowing the mare to facilitate the stallion's dismount by walking forward reduces the risks of unwelcome associations with copulation.

Among the human interventions that are frequently employed to modify libido, pharmaceuticals and **castration** are perhaps the most important. The social rank of a stallion is surprisingly static after gelding,

but **testosterone** concentrations of stallions have been found to drop when males are housed together in what amounts to an analogue of bachelor bands found in the free-ranging state. So, if safety can be maintained, increased contact between mares and stallions can improve herd fertility and reduce the prevalence of unwelcome behaviours in stallions. Behaviour problems in the stallion, including failure in reproductive behaviour, **self-mutilation**, aggression and other handling problems, generally reflect the failure of management regimes to meet the behavioural and physiological needs of stallions and, indeed, mares.

Masturbation, previously a source of concern to many stallion owners, who linked it with a variety of outcomes ranging from low sperm counts to social disgrace, is part of the normal **ethogram** of male horses. However, stallion rings (constrictive circumferential bands that prevent vascular engorgement of the penis) are still sometimes used and bring with them the inherent risk of abrasions and scarring. Teaser males may be used for oestrus detection, but are usually prevented from breeding by barriers, because they are of insufficient height or have been vasectomized. The welfare of such stallions is regularly questioned, especially where surgical procedures (such as **circumcision**) are used to render a stallion unable to consummate sexual behaviours.

Mares in the free-ranging state can be categorized as either social dispersers (so-called mavericks that leave the natal band spontaneously), loyal to a single stallion or part of a multistallion band. They tend to form strong alliances with their daughters and other resident females and usually take a leadership role within a natal band, perhaps because they tend to be resident longer than any male and therefore have the most mature bank of information about the band's home range.

Being seasonally polyoestrous, mares show a cyclical active oestrus (7.1 ± 4.2 days) and quiescent dioestrus (16.3 ± 2.9 days) throughout the breeding season (152 ± 50 days). Oestrus in the mare is characterized by **courtship behaviours** such as abrupt halts during locomotion, raising of the tail (before being mounted or after being mounted), clitoral winking (especially during teasing), frequent urinating and precopulatory behaviour such as sniffing and nibbling. The role of mares in courtship, especially in approaching and following stallions, has frequently been underestimated, but it is now recognized that mares have a significant influence on the success of matings.

Some mares may exhibit oestrous behaviour during pregnancy because of high **oestrogen** levels from accessory *corpora lutea*. More commonly, a pregnant mare's behaviour does not change markedly during **gestation** until immediately prior to **parturition**, when obvious changes include increases in both walking and recumbency. Foalings tend to occur at night and

P.322

regularly involve some form of social isolation, perhaps to avoid **mis-mothering**. Social attachments, such as the bonds that develop between mare and foal, hold equine social units together. In the free-ranging state it normally takes 2 weeks of close proximity and frequent interactions for the foal and mare to consolidate their bond. The spatial relationship within the dyad can be characterized by the number of 'approaches' and 'partings' made by either member. Although initially the mare's bond with the foal is much stronger than vice versa, foals do more work to maintain contact with their dams, but this tendency declines as they approach **weaning** age.

In free-ranging horses, weaning is very gradual and mares may permit **suckling** by yearlings even when they have a new foal at foot. Weaning in domestic contexts, on the other hand, is often marked by abrupt changes in the foal's social environment and nutrition. To reduce weaning stress in a herd situation, mares can be periodically removed so that foals are left together in familiar surroundings. Although creep feeding of foals prior to weaning may reduce some forms of distress and optimize the post-weaning growth rate of the foal, it has been linked with the emergence of oral stereotypies. Antacid supplements appear to have merit in reducing such undesirable sequelae.

Horse training and handling have undergone a recent renaissance, with ‘horse whispering’ (horse handlers who challenge traditional horse-handling dogma and advocate novel and often gentle methods of training) showing how effective subtle handling can be in the foundation training of young horses and the retraining of older horses that have developed unwelcome responses. Central to their message is the importance of paying attention to the body language of horses whenever working with them. Whether they realize it or not, good handlers of horses are students of equine behaviour. They recognize that horses rarely forget aversive procedures. By keeping horses as calm as possible, they ensure that the type of restraint required for current and future handling can be kept to a minimum.

Behavioural wastage in the horse industry is unacceptably high, largely because effective training of horses is compromised by widespread ignorance of learning theory among riders. Furthermore, equine education is clouded by the implication that horses have some moral role in their own training and by the use of opaque terminology and **anthropomorphisms**. Contemporary horse-training dogma provides numerous obstacles to effective equine learning, such as training too many responses simultaneously and one signal overshadowing (a process whereby the presence of a second stimulus interferes with learning an association between the target stimulus and some important event) another. If novice riders were coached in learning theory and recognized the principles of operant conditioning before learning to develop an independent seat on a horse, the industry and many riding school horses would benefit.

Horse training and management techniques are notoriously resistant to change. However, the scientific data supportive of the case for bitless bridles, not least as a means of showcasing outstanding horsemanship, and for podiatry that avoids the use of metal shoes (because they may have deleterious orthopaedic consequences) are emerging.

To resolve learned responses, equine behaviour therapy relies on: (i) consideration of the ethological relevance of unwelcome behaviours; (ii) elimination of pain and discomfort as proximate causes; and (iii) application of learning theory. The reasons behavioural modification fails include inconsistent application of learning theory and a lack of reconciliation of the task required of the horse and its physical ability to comply.

Horse training

Despite their now-diminished role in agriculture and warfare, **horses** have a new and highly popular role in equestrianism for **sport** and leisure in the developed world. For example, horse racing codes include races for Thoroughbreds, Standardbreds, Arabians, quarter horses, ponies and endurance horses. Other equestrian pursuits include polo, polocrosse, dressage, eventing, showjumping, equitation, **hunting**, many showriding codes (turn-out, riding classes, pony and hack classes, side-saddle, etc.), Western riding, Australian stock horse, games (barrel racing, etc.), rodeos, cattle cutting, gaited-breed riding, pony club, many carriage-driving codes, myriad show breed classes and leisure-riding activities.

Ever since humans first domesticated the horse, their interactions have involved training schemes that engaged the animal's perceptive and motor abilities for human purposes, such as the keen olfactory sense of canids and the locomotory abilities of equids. Although correct and successful horse training methodologies comply with the general principles of equine learning, horse training has traditionally been understood from an anthropomorphic viewpoint in which the horse has some voluntary involvement and is motivated by benevolence or malevolence. One of the problems with **anthropomorphism** is that it embraces the possibility that horses can be held responsible for their behaviour. One of the problems contributing to such notions of culpability is that there is no consistent descriptive terminology among horse enthusiasts. Furthermore, an appreciation of the learning theory that forms the broad base of contemporary training in many other species such as guide dogs and animals in **zoos**, **circuses** and oceanaria is largely absent in contemporary systems of equitation, training, coaching and manuals of horsemanship.

Correct horse training involves **habituation**, operant conditioning and classical **conditioning**. During the earliest phases of horse handling, which may take place soon after birth (**see: Imprint training**) or at weaning time, horses habituate to their surroundings, to humans and their movements as well as to training paraphernalia (e.g. head **collars** and lead reins). Because much of the apparatus used to facilitate training in horses operates through various levels of pressure, negative **reinforcement** is the chief operant learning process. Thus the trainer targets a particular response, and maintains or increases the pressure until the onset of that targeted response. For example, the horse is negatively reinforced to move forward when anterior lead pressure

P.323

occurs, because the lead pressure is removed immediately after the animal steps forward. The optimal moment to release the lead pressure is after the horse's forelegs have moved forward. Similarly, the horse learns to decelerate its forward motion from lead pressure in the posterior direction.

The rules of negative reinforcement also apply 'under saddle' when the horse moves forward from the pressure applied by the rider's legs. The forward movement is then classically conditioned to occur in response to lighter versions of the pressure signals from the rider's legs, or perhaps seat movements or voice. The two reins are used negatively to reinforce decelerations when a release of pressure occurs as soon as the horse decelerates. Decelerations are classically conditioned to be elicited from light rein signals and bracing movements of the rider's seat or from vocal commands such as 'whoa'. The horse learns to turn its forequarters through the pressure and release of the single rein, so that tension in the right rein results in the right turn, and in the left rein results in the left turn. Some trainers use the rein contralateral to the turn direction to turn the horse in what is known as a neck-rein or an indirect rein, where the rein is moved toward the midline of the horse and pressed against the lateral aspect of the neck. In some equestrian codes horses are also trained to move their hindquarters laterally. This response is elicited by the pressure of only one of the rider's legs and, again, the movement is negatively reinforced by the removal of that pressure. Eventually, the sideways movement is classically conditioned to be elicited from the mild pressure of the rider's single lower leg.

Harness horses learn to go forward through negative reinforcement of the driving whip on their rump; they are then classically conditioned to move forward after a verbal command. In addition, they must habituate to the vehicle they pull. Some horses habituate poorly to visual stimuli to their rear, so harness trainers frequently use 'blinkers', eye-covers that allow only forward vision.

Most horse trainers and coaches fail to recognize the negative reinforcement that is inherent in the early training of leading signals. Instead, they cite compliance and responsiveness as evidence of the horse's willingness to please. In fact, horses that have learned via classical conditioning to respond to light signals have, nevertheless, initially learned through negative reinforcement.

Positive reinforcement can assist in shaping and maintaining stable responses. The methods of positive reinforcement may involve primary reinforcers, such as food, or caressing the horse at the base of the withers (an area where rubbing is known to lower heart rate), or conditioned secondary reinforcers such as verbal praise. Secondary positive reinforcement occurs when an inherently neutral (and therefore unrewarding) stimulus such as the trainer's voice is paired with a primary reinforcer.

Stimulus **generalization** also occurs in horse training where the animal is able to discriminate less context-specific signals from the rider, driver or handler and respond appropriately. Horse people observe that this tends to occur largely in older, more experienced animals, so generalization appears to be an ontogenetic process.

Because of the invasive nature of negative reinforcement, horses are susceptible to **stress** and **conflict behaviours** when the pressures are disproportionate, uncomfortable or distressing, or when they are not released at all, not released at the correct moment or released inconsistently. The solution lies in the correct application of negative reinforcement, both at the outset of training and in the repair of the unwelcome stimulus-response relationships.

Because the incorrect application of negative reinforcement causes stress in animals, it would be beneficial if trainers learned the correct application of negative reinforcement. Many people are becoming attracted to the use of positive and, particularly, secondary positive reinforcement as a viable alternative in horse training; this includes techniques such as '**clicker training**'. Although there is little evidence that the use of secondary reinforcements can rehabilitate horses suffering from negative reinforcement training errors, it could be more effective than regular positive reinforcement, because a secondary reinforcer may be delivered at the precise moment of the correct behaviour, whereas primary reinforcers can often be delivered only after some delay.

Many horse riders and trainers appear to assume that subjective mental states account for the horse's responses. For reasons yet to be established, equestrian technique has been more influenced by the science of ethology than the science of **psychology**. In her review of animal cognition, Shettleworth (2001) points out that the diversity of approaches between ethology and psychology, in understanding the animal mind, present a dyadic problem in the analysis of behaviour. Whereas ethology arose mostly in Europe within the context of zoology, with its strong emphasis on evolution, psychology emerged in North America without the influence of any evolutionary perspective that characterizes zoology. Meanwhile, despite its relevance to behaviour modification in humans and animals, the demise of behaviourism in the latter part of the 20th century meant that horse trainers were shielded from learning about it. So it is perhaps not surprising that the New Age horse trainers were more influenced by the *prima facie* appropriateness and relatively simplistic interpretation provided by ethology in understanding horses. In an appealingly simple traditional construction, ethology reveals the existence of various **innate** processes, such as the hierarchy, social and herding instincts, and others, but makes little reference to the more proximate mechanisms, such as reinforcement, that establish such behaviours. The pitfall of the singular ethological approach is that it fails to explain the proximate mechanisms of ethological phenomena, and this in turn promulgates inappropriate expectations (via subjective mental interpretations) to be placed upon the animal. Many New Age horse trainers have been influenced by the ethological approach, and place a great deal of emphasis on the equine 'peck order', emphasizing that: the horse should be made to see the human 'as a leader'; the human should be *dominant* over the horse and, conversely, the horse should be *submissive* to humans; and the horse should be taught to 'respect' humans and not to invade the human space. The common terms that unite the New Age methods include 'respect', 'willingness', 'submission', 'leadership' and 'attitude'. In human-horse interactions, these concepts may have negative **welfare** implications for horses and can lead to punitive measures that bear little relation to the original symptomatic behaviour.

The horse wastage statistics for the horse industry are high, and significant wastage of performance horses is for

P.324

behavioural reasons (Ödberg and Bouissou, 1999). It is also significant that the statistics on wastage came from countries with well-established equestrian traditions, so there is no reason to believe that figures would be significantly different in other countries.

In addition, there is a considerable degree of danger posed by horse riding in modern training contexts. For example, in the USA the national horse-related death rate is 219 per annum, with most deaths occurring in younger females and middle-aged males (Bixby-Hammett, 1992). About 20 Australians are killed as a result of horse-riding activities each year and a further 3000 hospitalized. So the annual death rate from horse riding is about one per million head of population. It is widely reported that most deaths are of young female amateur riders (which correlates with a greater proportional representation in amateur equestrian pursuits by women), followed by older (age range 30-50 years) professional male riders. In terms of deaths and injuries, horse riding is more dangerous than motorcycle sports or car racing, and as dangerous as rugby.

The danger inherent in human-horse interactions reflects the fact that a horse weighs about 600 kg, can gallop at 65 km/h and has a powerful and dangerous kick. While most researchers rightly suggest that reductions in death and injury rates in horse-related activities would be achieved with increased supervision of children and the use of safety equipment, such as riding helmets and vests, few point to horse training or behaviour modification as a potential alleviating factor. Cripps (2000), however, sees the situation differently: 'It's important also to learn about how horses behave'. Clearly, the wastage statistics and the human injury statistics suggest that coaching in learning theory for horse people and, particularly, for trainers in all disciplines, is an essential step in the development of modern equestrianism.

Horse whispering

Traditionally, force has been used in horse training in the belief that human dominance and equine submission are critical to success and the development of so-called 'respect' on the horse's part. As a

result, many horses learned unwelcome evasions, resistances and flight responses. Historically, horse whisperers might then be called upon to remediate such horses. They locked themselves in stables to weave their magic and emerged with impressive results but no intention of divulging the techniques used. Their deftness and the absence of any apparent **vocalization** as part of their practice gave rise to the beguiling notion of their needing only to whisper to horses to get the desired results. It was to their advantage to let the uninitiated believe that whispering, rather than training, was involved.

Recently, the use of applied learning theory has begun to expose simple, humane and effective mechanisms in horse training. As we appreciate how to communicate with horses sensitively and consistently, misunderstanding and misinterpretation by both parties will diminish. These advances are being matched by greater sharing of knowledge among practitioners. As an example, in the latest wave of 'natural horsemanship', trainers use techniques similar to the whisperers of old but do so in public. Natural horsemanship trainers are often talented observers of horse behaviour who respond consistently and swiftly to subtle cues during training. They apply **aversive** stimuli to prompt a flight response and then, when the horse slows down, move towards them, or offer space-reducing affiliative signals; they remove the pressure and thus negatively reinforce the desired responses. Learning theory can be used to explain almost all of the behavioural modification that goes on in such contexts.

Numerous horsemen have demonstrated their ability to exploit the marketplace and, largely without reference to learning theory, teach their methods for commercial reward. Unfortunately, not all followers of these methods are as effective as the good trainers. Poor technique can lead to disappointing results and eventually frustration in practitioners, which may result in abuse, confusion and **conflict behaviour** in horses. Scientific assessment of how novel techniques operate and questioning of how the language relating to horse training and riding relates to what is known through **psychology**, **ethology** and veterinary science, has helped to deepen our understanding of the benefits and limitations of these techniques. Burgeoning demand for best practice that is underpinned by empirical data rather than belief systems has prompted the emergence of equitation science as a scientific discipline in its own right.

House-soiling

House-soiling, or urination and **defecation** in inappropriate places, is one of the most common problems reported by people who live with **companion animals**. Feline **urine** spraying is also commonly stated as a house-soiling problem, but is functionally distinct.

Urination is the natural process by which the bladder is emptied, while urine spraying, also a natural behaviour, is a form of scent deposition that helps to demarcate **territory** and signal social or reproductive status. In **cats**, spraying is generally performed from a standing or squatting position, releasing a small amount of urine against a vertical surface. Urinating involves squatting and releasing a large quantity of urine on to a horizontal surface.

Dogs also commonly urine mark, especially males, who will typically cock their legs on to vertical surfaces and release a quantity of urine. Subsequently, dogs passing the marked spots

P.325

obtain information by sniffing the odorous deposits that are conveniently located at nose height. Leg lifting, a behaviour normally observed in sexually mature male dogs, emerges in juveniles with increasing

testosterone production. Some females are also observed to take up this leg-cocking practice while others will squat and, as males do, over-mark urine scents left by others.

House-soiling has a number of triggers, including physiological and behavioural factors. Medical problems causing house-soiling include kidney and urinary problems, and all house-soiling problems should be medically investigated before, or at the same time as, behavioural causes are considered. Feline lower urinary tract disease, for instance, may be extremely serious, even life-threatening.

Behavioural causes of house-soiling include dislikes or preferences for certain substrates, such as particular litter types or grass as opposed to concrete. **Anxiety**-related causes, such as the presence of other animals, may also result in inappropriate **elimination behaviours**.

Treatment includes implementing a behavioural treatment programme through:

- Appropriate areas and/or times for elimination, e.g. cats may require more litter trays.
- Different positioning or different litter.
- Dogs may need to be taken out more regularly on to suitable substrates.
- Appropriate cleaning methods to avoid reoccurrence by animals that tend to return to odourous spots.
- Neutering of cats and dogs to reduce marking behaviour.
- Reducing anxiety by keeping routines constant or, in the case of **separation anxiety**, gradually building separation tolerance and using distractions such as toys or food treats when the owner leaves. Where anxiety is the cause of house-soiling problems, medication such as antidepressants may help, in conjunction with a behaviour treatment programme.

Housing

When animals are kept for farming, research, teaching, entertainment or as **companion animals**, they usually require housing. There is immense variation in the design and construction of housing according to the requirements of the animals, their keepers and the reasons for the animals being housed.

Farm animal housing

Farms are businesses, and therefore economics are often the governing factor in decision making. A major cost of many farming operations is the housing and therefore it follows that, to minimize farming costs, housing is often as basic as possible. This relates to not only the quantity of space, but also the quality of space. As a consequence, the vast majority of farm animals are housed in small, barren, minimalist environments (**see: Intensification of animal production**). In contrast, some farm animals are reared with access to large amounts of open, varied space (extensive systems), with relatively little housing because, under some circumstances, this is the most economical method, or because this can attract premium prices when the animals or their products are sold at the market place.

Intensive housing systems

Globally, the animal species farmed in greatest numbers are meat hens (broilers), layer hens (**see: Chicken**) and **pigs**. Being the most widely farmed species, the greatest economic pressures have been brought to bear on the housing of these, resulting in the widespread adoption of intensive systems for them. This drive for economy of animal production has been so great that, in the case of **laying hen**

housing, it is legal in some countries to house birds in cages that provide each animal with floor space less than a sheet of A4 paper. The hen will be housed in a cage this size for its entire life, which might be several years. The cages usually have a wire mesh floor and sides, provide food and water (except when these might be withdrawn for several days during **forced moulting** to reinvigorate production) and little else to interact with other than cage-mates.

While such highly intensive systems offer some benefits to the animals (protection from **predation**, environmental variables usually maintained within comfortable limits, generally a clean environment, receipt of appropriate medication), they prevent the performance of many highly motivated behaviours, which leads to **frustration** and the performance of **abnormal** behaviour such as **feather pecking**, **cannibalism** and **stereotypies**.

Intensive housing systems sometimes involve highly restrictive environments. Modern domestic sows can be very large and are often highly fecund. However, they are not always particularly good mothers. Piglets are sometimes cannibalized or injured by their mother, or crushed because she has trouble rising and lying due to her great weight. Parturient sows can also be highly aggressive towards humans. As a consequence of these factors, many preparturient sows are placed in **farrowing crates**. These enclose individual sows in metal frames that allow them to stand and lie, take one or two steps forward or back, but they prevent her from turning around or being able to attack **stockpersons**. The sow is placed in the farrowing crate a day or two prior to the expected birth, and remains in there until several days after. There have been attempts to design less restrictive farrowing crates: some of these are circular, have a rail around the edge to reduce the possibility of the sow crushing her piglets when she lies down, and a creep area into which the piglets can escape but which the sow cannot enter.

Intensive housing systems can be very large and contain many thousands of animals. In the UK, a single house of caged layer hens might contain over 100,000 birds, and a flock of 20,000 broiler chickens might be reared in a single house. Due to scales of economy, there are often several such houses on a farm, meaning that hundreds of thousands of animals could be on a single farm, often under the charge of only a small number of stockpersons.

Semi-intensive housing systems

There have been recent attempts to develop housing that offers the benefits of both intensive and extensive housing systems for farm animals. The most notable of these is the development of 'furnished' cages for layer hens. They are

P.326

designed to incorporate key **welfare** features such as increased space allowance, a nesting box, perch, dust bath and scratching areas. Research has shown that hens are highly motivated to perform behaviours associated with these key features, and it is believed that providing them produces a housing system that offers all the benefits of intensive cage systems and some of the benefits of extensive systems. In Europe, legislation has been passed stating that conventional cages for laying hens should be replaced by furnished cages by 2012. These systems are designed to house colonies of various sizes, some as small as four or five birds per cage, whereas others have larger colonies, e.g. 60 hens. Concerns remain about the welfare of hens in some of these systems, especially with regard to feather pecking, particularly for larger groups.

Other semi-intensive housing systems have been developed such as the Alex Stolba family pen for pigs, which aims to keep pigs together as a family unit throughout their production life. These systems require a high standard and effort of husbandry and management, which is possibly why they have not been adopted to any great extent.

Extensive housing systems

Some animal housing systems have always reared animals in large areas of natural space, e.g. range **sheep** or **cattle** in the USA or Australia. Essentially, the animal lives a free-roaming life and might be handled only once or twice a year. These systems are still operated because the minimal amount of housing required means the overall farming method remains viable. In more recent years, there has been a trend to reverse the confines of intensive farming, particularly for pigs and poultry, and give animals access to considerably greater amounts of space, although not the amount that would be given to range animals. This has advantages for welfare, indicated by an increased behavioural repertoire and more species-specific behaviours; however, the animals incur an increased risk of other welfare compromises such as disease or predation.

Laboratory animal housing

Economic concerns have also had a considerable influence on the design of housing for **laboratory animals**. For humans, it is essential that laboratory cages are inexpensive, easily cleaned, practical and have great longevity. In addition, from the scientist's point of view, it is essential that the animals' environment remains unchanged during studies, or at least is highly controlled. Very often, this requirement extends between studies. The easiest way of achieving all these requirements is to make the housing as simple as possible. As a consequence, laboratory animal housing is generally small, barren and minimalistic. For example, laboratory mice are typically housed in plastic cages that might be approximately 15 × 30 cm, food and water are supplied through the wiremesh cage roof, and the floor might be covered with 1-2 cm of sawdust. Several mice will be kept in a cage of this size, and they will receive no stimulation other than that which they receive from the scientist as the procedure for which they are being kept.

This type of intensive housing clearly prevents many species-specific behaviours, some of which are demonstrably highly motivated, e.g. for mice, tunnelling, **nesting behaviour**, extensive **locomotion**. Other laboratory species, perhaps most notably those usually considered as companion species under other circumstances, are likely to be housed in less minimalistic conditions in the laboratory. **Cats, dogs, rabbits, horses**, etc. might be offered more playthings, a greater variety in their diet, a more complex environment, perhaps even access to the outdoors; however, the majority of laboratory animals will still be housed for a great proportion of their time in small enclosures that are only a few of their body lengths in any one direction, and containing little else other than food, water and **conspecifics**.

The small and minimalistic nature of laboratory housing has notable effects on the behaviour and physiology of the animals they contain, indicating that animal welfare is compromised. This type of housing can also create a secondary concern in that the biological functioning of the animals can be so abnormal that the validity of the science is reduced, thus negating the main purpose for housing the animals in the first instance.

Home-cage behaviour

Mice in standard laboratory cages self-administer greater quantities of anxiolytic (a drug that reduces **anxiety**) than mice in larger, enriched cages, indicating that underlying anxiety might be greater in animals in standard laboratory housing. When kept in standard housing, bouts of spontaneous nocturnal locomotion by mice are less intense and distinct than seen in mice in larger cages, and both cage shape and size can influence the mating behaviour of male **rats**. Standard laboratory cages are either white or transparent; however, it has been shown that the home-cage colour can influence food intake and body weight of mice.

External tests

Standard laboratory housing can influence a range of responses outside the home cage. In tests of emotionality (e.g. elevated plus-maze, open-field, shuttle box), **rodents** from standard housing often behave in a manner indicative of being more anxious or fearful than animals from enriched or larger cages. Jumping spiders from smaller cages progress less distance in a searching test and respond less vigorously to videotaped prey. Spiders from non-enriched standard cages are less active in the open-field test and only respond to videotaped prey from shorter distances.

Effects of laboratory housing on sensory development and neurogenesis

It is usually assumed that the sensory development of animals in standard laboratory housing is normal, and therefore any responses dependent on these senses will also be normal. However, mice raised from birth in larger, enriched housing have 18% better visual acuity than mice from standard housing. The effects of standard housing on behaviour can occur due to influences on neural development and plasticity. Enriched cages can enhance neurogenesis or, stated conversely, standard housing can limit neurogenesis. The implications of this effect can be profound because the links between neural development, behaviour and physiology are still not greatly understood. Certainly, there are many reports that enriched

P.327

cages can improve recovery from brain trauma compared with standard, barren housing.

In transgenic mice that develop Huntington's disease, the decline in performance in the RotaRod test and the loss of peristriatal cerebral volume in the **brain** is considerably quicker for animals in standard housing compared with enriched. In wild-type mice that do not develop the disease, enriched housing considerably enhances performance in the RotaRod test, although there is no improvement of grip strength, indicating that the enhanced performance is not due to increased muscular strength. It has been suggested that enriched housing alters gene expression in the normal mouse brain, which modulates the course of the disease.

Effects of laboratory housing on physiology

Several studies show that characteristics of standard laboratory housing can influence physiology. Compared with animals in smaller, standard housing, daily energy expenditure and food intake of mice in larger cages can be greater or lesser, depending on the species. The mean baseline temperature of **hamsters** is significantly higher in animals housed in small cages compared with larger, and the reaction to fever-inducing lipopolysaccharide is highest in animals housed in large cages and smallest in animals in small cages. In studies of rats housed in cages with grid floors, plastic floors or bedding, there are significant differences in systolic and diastolic **blood pressure**, **heart** rate and body temperature.

Effects of the social environment

Standard laboratory housing often entails housing gregarious animals in isolation or solitary animals in groups. Housing animals contrarily to their normal social behaviour can result in responses that almost certainly reduce their welfare and the validity of the data gained from them. Singly housed hamsters (normally a solitary species) recover more quickly from mercury poisoning than group-housed hamsters, which show a reduced body weight gain, possibly due to high **social stress** elevating their susceptibility to intoxication. Plasma triglyceride levels and food intake are lower in isolated rats than in grouped rats, although there is no difference in body weight. Singly housed mice have higher heart rates and tend to have a reduced body temperature, although there is no difference in activity. Compared with group-housed mice, singly housed animals are smaller, have less soft lean tissue and bone mineral content, and lower bone mineral density. In terms of behaviour, singly housed rats are more active under several conditions of environmental novelty, but have an increased latency in an emergence test, indicating

greater fearfulness. In addition, it appears that singly housed rats are less able to learn a task reversal than group-reared rats.

Designing more appropriate animal housing

Concerns about the effects of animal housing, whether these are for animal welfare or scientific validity reasons, can be avoided by redesigning housing from less anthropocentric and anthropomorphic viewpoints.

Understanding the animal's senses

To design and build more appropriate animal housing, we should try to reduce our anthropocentricity and consider how the animal perceives the environment with its own senses (**see: Anthropomorphism**). Sometimes this requires fundamental research on which sensory modalities the animal possesses, how well developed these are and their importance to the animal. This knowledge can then be introduced into applied studies of how the housing might affect these senses and possible methods of rectification if they raise concerns.

One example of developing this knowledge and its application is bird vision. Birds have different vision from humans: they can see in the ultraviolet range whereas most normal adult humans cannot, and birds have a much higher critical flicker fusion rate (the rate at which a flashing light is perceived to be a steady light). Birds are often housed in rooms illuminated by fluorescent lamps. These emit very little ultraviolet (UV) light and flicker on and off at 50-200 Hz. This means that the bird's vision is potentially distorted by the absence of ultraviolet wavelengths, and the birds are probably perceiving fluorescent lamps as flashing on and off. Behavioural studies have shown, however, that even if birds are perceiving fluorescent lamps in this way, it does not appear to be particularly **aversive** to them and therefore is unlikely to be a great welfare compromise. Fluorescent lamps that emit UV have recently been developed for birds and are now commercially available.

Understanding the animal's natural behaviour

Studies on the behaviour of animals in their natural environment can reveal that the housing we provide is often inappropriate. Many natural behaviours are thwarted by standard housing, e.g. burrowing by laboratory mice, nest building by farmed pigs, dust bathing by farmed hens (**see: Frustration**). It is not until we study their behaviour in a more natural environment that we realize that, despite years of domestication and hundreds of generations of housing under artificial conditions, the animals have retained the motivation to perform many of these behaviours.

Understanding the animal's motivation

If certain characteristics of housing are desirable to an animal, it will choose these in a preference test, or avoid them if they are undesirable. Similarly, we can measure the strength of **motivation** that the animal has to gain access to, or avoid characteristics of, the housing. This method is based on the premise that animals (usually) behave in ways that maximize their welfare, and that the more strongly motivated an animal is for some aspect of its environment, the more likely it is to suffer if we do not provide it. In this way, we can assess whether we should be providing animals with larger housing, grid or solid floors, nestboxes, etc.

Human-animal bond

The human-animal bond describes the dynamic social relationship that exists between people and non-human animals and, while this can exist with any species, most attention has been paid to the relationship with **companion animals**, as this is where there are most clearly mutually beneficial outcomes from a **bonding** relationship. Humans have the potential, at least in theory, to develop a bond with any species of vertebrate or invertebrate with which they have contact, but the nature of the resultant bond will vary depending, at least in part, on the ability of the species concerned to reciprocate within the relationship and the degree of **empathy** and understanding demonstrated by the human partner. Companion animals are often kept primarily for social or emotional reasons rather than for economic purposes (Laurent, 2000). Relationships with non-human animals differ significantly from **conspecific** human relationships in that there tend to be fewer social and potentially psychological barriers applied by the human, since non-human animals appear non-judgemental and their attentiveness to their caregivers is in most cases largely unconditional.

The study of the human-animal bond comes within the wider realm of human-animal interactions, which is covered within the discipline of **anthrozoology**, and much of our knowledge in this field has focused on the benefits to people of developing affectional bonds with companion animals (**see also: Affiliation**). These benefits can be psychological and/or physical, and investigations into beneficial physiological responses, which reflect the interface between these effects, have been the focus of a numerous studies. Physical benefits may be derived through many routes; for example, as a result of an increase in exercise encouraged through **play** or shared exercise (e.g. walking a dog or horse riding), or as a result of decreases in **blood pressure** associated with the calming effect of tactility and/or the emotional support provided by contact with an animal (De Mello, 1999; Friedmann *et al.*, 2007). Psychological benefits include encouragement of social interactions, provision of social support, reducing loneliness as well as the direct provision of perceived friendship and unconditional love.

For a human-animal bond to be considered successful, the benefits of such a relationship must outweigh any potentially detrimental effects for both of the individuals concerned. Explanations of the balancing of both the positive and negative aspects of the human-animal bond incorporate concepts relating to **biophilia**, **economics of behaviour** and **attachment** theories. Animals are generally provided with food,

shelter, companionship, protection and medical prophylaxis/treatment in return for the fulfilment of the emotional, social or utilitarian needs of their owner or caregiver. The financial, emotional and social costs of caring for the animal should not exceed the perceived benefits, because this may jeopardize the quality and/or longevity of the resultant bond; however, one major challenge is identifying a common currency for this equation.

Not all consequences of the bond are positive. The relationship is dynamic and influenced by internal as well as external factors; for example: (i) the **personality** and experience of the individuals concerned; (ii) the **health** of the partners, including their physical and mental well-being at any given time; (iii) environmental circumstances, including household membership in relation to people and other animals; and (iv) relocation or periods of **stress** and bereavement. Where owner expectation is not met, either because the animal does not fulfil their requirements or the work involved in caring for the animal exceeds that anticipated by or available from the owner, the risk of the relationship breaking down is increased, since it is ultimately the human that controls the continuity of the relationship.

When the owner fails to understand or provide for the husbandry, behavioural and welfare **needs** of the animal, the risk of that animal experiencing physical and/or mental stress is increased. This may manifest itself in either physical illness or behavioural disturbance, which may strain the bond with the owner(s); rarely will a socially developed species like a **dog** leave its owner, but this may not be true for a species like a **cat**, with access to a free environment potentially including other humans.

Various scales have been developed in an attempt to measure the human-animal bond (e.g. Pet Attitude Inventory (PAI), Lexington Attachment to Pets Scale (LAPS), Pet Relationship Scale (PRS), Monash Dog Owner Relationship Scale (MDORS) and Companion Animal Bonding Scale (CABS)). These tend to evaluate the positive perceptions in the relationship, but there are difficulties or unanswered questions relating to their validity. These tend to relate to: species variation and the resultant differences in the type and quality of bond possible; asymmetry of the bond and the assessment of the perspective of both the human and other animals within the relationship; and **reliability**, construct **validity** and feasibility for practical application.

The effects of problem behaviour on the human-animal bond are of increasing interest to those working within the veterinary behavioural field. The specific influence of the development, management and overall impact of different behaviour problems on both the stability and success of the human-animal bond has been neglected historically and may provide useful insights into the difference between enduring versus failing human-animal bonds. Evaluation of animal behavioural problems may provide a useful guide to the evaluation of the bond from the animal's perspective, as these can develop in physiologically normal animals as a result of their inability to cope with the demands placed upon them by both their social and physical environments.

There is growing recognition within the veterinary profession that, in order to fulfil its role in providing care for the many species of companion animals, it must recognize and support the human-animal bond. This support should include provision of advice on animal husbandry, behaviour and welfare so that problems can be prevented as well as treated. Attention should be paid to the provision of emotional support when animals become ill, require surgery or hospitalization and, particularly, before and after the decision to euthanize an animal. Thus, veterinary clinics should be designed to provide facilities for all members of the family to visit, especially when

P.329

animals are hospitalized, without disrupting their essential function.

Humane societies

A humane society is an organization that aims to stop and prevent animal (and/or human) **suffering**. Animal-centred humane societies include such large organizations as the UK's Royal Society for the Prevention of Cruelty to Animals (**RSPCA**), the **Humane Society of the United States (HSUS)** and the World Society for the Protection of Animals. There are also a great many local humane societies that are not affiliated to any of the large organizations and that have similar aims but perhaps cover a much smaller geographical area or a target species.

(JNM-F)

Humane Society of the United States (HSUS)

The Humane Society of the United States (HSUS) was founded in 1954 in order to promote the protection of all animals. Headquartered in Washington, DC, and with over 10 million members, the HSUS is the largest animal protection organization in the world, working primarily in the USA but also internationally to reduce animal **suffering** and create meaningful social change for animals by advocating public policy, investigating cruelty, working to enforce existing laws and educating the public.

Humanism

Humanism as a philosophy of life stresses the importance of living ethically through reason and conscientious compassion. Most forms of humanism are civic minded and place a high premium on active participation in social justice issues. Some variants are committed to improving the lives of animals and our relationship with nature.

Hunger

'Hunger' can be used to describe a craving, most often applied to the sensation of needing food following a period of nonfeeding in order to achieve or maintain **homeostasis** and ideal body mass (total body fat stores plus circulating concentrations of energy substrates). Hunger was traditionally described as a 'homeostatic drive', a behaviour (under negative feedback control) that initiated feeding as a direct result of changes detected within the animal's physiology. The modern view now regards hunger as a '**motivation**' (in accordance with the idea of those specific drives once thought responsible for different aspects of behaviour being superseded by the notion of 'motivational state'), whereby behaviour is determined by the **brain** as a result of both internal motivation and the animal's perception of environmental stimuli (external causal factors such as smell and food proximity).

It is misleading to think of hunger as a unitary variable, measurable along a single scale (e.g. 'low' - or 'high' - level hunger), as the relationship between hunger and behaviour is not direct. There are many different aspects of hunger that may alter an animal's **feeding** behaviour - e.g. specific hunger for a deficient compound or anticipation of physiological changes demonstrated by the existence of habitual feeding times in animals provided with food *ad libitum*. The development of 'state-space representations of motivational systems' has proved advantageous in the portrayal of hunger as a multidirectional vector, with axes representing fat, protein, carbohydrate, etc.

The sensation of hunger, and its associated physiological state, can normally be temporarily alleviated by food consumption. The feeling of satisfaction and sensation of fullness following a meal, together with a lack of desire to eat, is termed '**satiety**', the opposite of hunger. 'Appetite' is often used synonymously with hunger, yet may be considered a more hedonic term, encompassing a desire for food (perhaps certain food items) and the enjoyment of eating, and as such is widely influenced by psychological factors.

The physiological system controlling food intake (via hunger and satiety) is extremely complex, involving numerous internal and external factors, and comprising the means for both short-term (daily) and long-term (monthly) energy management. The currently accepted model is of a central feeding system whereby two major peripheral systems, a short-term satiety system (transmitting meal-related signals) and a long-term system (concerned with adipose tissue and overall energy balance of the body), convey information to the **hypothalamus** (Jensen, 2001).

The hypothalamus functions as an integrating relay centre in the control of all eating behaviour in both mammalian and non-mammalian vertebrates. It receives nerve impulses from other parts of the brain and from a variety of sensory receptors, including chemoreceptors, olfactory and taste receptors, and stretch receptors in the gastrointestinal (GI) tract. A cluster of **neuron(e)s** within the lateral portion of the hypothalamus has been termed the 'hunger centre', because stimulation of this area causes voracious feeding (even when an animal is full). A further cluster of neurons within the ventromedial hypothalamus has been termed the 'satiety centre', because stimulation of this region causes animals to stop eating, even if they have undergone starvation for several days. The 'hunger centre' appears to be constantly active but is subject to inhibition by the satiety centre. When food is freely available feeding initiation is likely to arise following a reduction in satiety signals and subsequent removal of feeding centre inhibition.

Short-term control of ingestion appears to be primarily regulated by neural signalling pathways emanating from the GI tract. Activation of stretch receptors (mechanoreceptors) as a result of gastric distension and chemoreceptors signals the

P.330

presence of food within the GI tract and initiates a reflex that activates the satiety centre and depresses the feeding centre.

Many animals (excluding cats) increase their food intake when the rate of glucose utilization in the brain falls. The glucostatic theory of hunger predicts that the rise in plasma glucose concentration (and the rate of cellular glucose utilization) that occurs during eating (as ingested carbohydrate is digested and absorbed) is detected by glucose receptors in the brain and leads to cessation of hunger. Conversely, in the post-absorptive period, plasma glucose concentration and glucose utilization decrease, removing the signal to the brain glucose receptors (reducing satiety centre activity and removing feeding centre inhibition), and stimulating the individual to eat. A detailed review of the role of glucose in meal initiation is provided by Campfield and Smith (2003).

Several peptide hormones have been identified as playing a role in food consumption. **Cholecystokinin** (released from the stomach and duodenum during eating and responsible for stimulating fat and protein digestion), **glucagon** (released by the pancreas when blood glucose is low), **insulin** (synthesized in the pancreas and responsible for initiating glucose uptake and storage) and **leptin** (released from adipose tissue) all act to suppress appetite. Ghrelin, conversely, demonstrates orexigenic (appetite-stimulating) properties, and as such is termed the 'hunger hormone'. When administered experimentally it has been observed to increase food intake in both humans and many other vertebrate species (although interestingly not in sheep). Ghrelin appears to be involved in short-term energy balance and meal initiation, because plasma concentrations peak before a regular meal and rise during fasting. Levels fall during feeding, then progressively increase to another peak prior to the next meal. Ghrelin also seems to play a role in long-term regulation of energy balance, as chronic administration of ghrelin in rodents leads to hyperphagia (excessive hunger) and weight gain. It also appears to stimulate gastric acid secretion and regulate GI tract motility. It is possible that hunger pangs (stomach rumbling) experienced during short-term fasting are due to increased gastric motility induced by ghrelin levels. Comprehensive reviews of this hormone and the many other afferent signals that regulate food intake are provided by Chaudri *et al.* (2006) and Higgins *et al.* (2007).

The mechanical activities of chewing and swallowing are known to influence the hunger centre. In dogs both oropharyngeal (tasting, swallowing) and gastric stimuli are necessary to induce satiety. The horse, on the other hand, appears to depend more on pregastric oropharyngeal signals as an indication of satiety than other species. Discussion of ingestive behaviour in the main domestic mammal species can be found in Houpt (1998).

Knowledge in this area of physiology has increased significantly over recent years, yet due to the complexity of the feeding mechanism it is highly likely that many signals, receptors (both location and nature) and the means of interaction and integration of the many component inputs remain, as yet, unidentified.

Although food intake is primarily controlled by a combination of receptors (glucose, mechano-, etc.), it is also strongly influenced by the reinforcement, both positive and negative, of such things as smell, taste and texture (food palatability). The smell of a favourite food can activate hunger even when, physiologically, we do not 'need' to eat. Animals fed to satiety on one kind of food will often continue feeding if given access to a wider range of foods. Wirtshafter and Davis (1977) demonstrated that rats given a normal 'rat food' diet and then provided with a variety of sweet and palatable foods (canteen diet) will eat a great deal more than usual and often became obese. Similarly, pigs show a marked preference for sweet substances and will eat more and gain weight when their food palatability is enhanced.

Many examples of nutritionally driven diet selection can be found in the literature (Forbes, 1995). Aversion to diets lacking sodium, calcium, thiamine, riboflavin and specific amino acids have all been

demonstrated in preference to an alternative that contains the missing component. Salt hunger is a particularly well-documented phenomenon in both humans and herbivores subjected to a sodium-deficient diet.

Reproductive state has a noticeable effect upon food consumption in female animals. **Oestrus** (and associated oestrogen levels) correlates with a reduction in food intake in several species (e.g. pigs, dogs, cattle), whereas increased food consumption occurs during pregnancy/**lactation**. Food intake is influenced thermostatically by the regulation of body temperature in response to environmental conditions, a process mediated through the anterior hypothalamus. Animals generally eat more in cold weather because more energy is required to maintain body temperature and thus prevent hyperthermia. Psychological elements such as stress or depression, disease, etc. can also effect food consumption. When the body temperature rises to pathological levels (as occurs during fever) food intake decreases, while cancer sufferers often demonstrate a debilitating lack of hunger (cachexia).

Hunger is an easy concept to understand but a difficult sensation to quantify in animals. Operant conditioning tests have been successfully employed as a direct measure of hunger but have the drawback of being impractical for use in large-scale studies or on production lines. Increased incidence of stereotypies in sows (e.g. biting, sham chewing and nosing/licking the feeder/floor when food is not present) have been found to be closely associated with restricted feeding levels, thus supporting the use of this method as an indirect indicator of hunger and feeding motivation (see Meunier-Salaun *et al.*, 2001). Feed-restricted broiler breeders also demonstrate behavioural abnormalities characteristic of hunger, including high motivation to feed at all times, hyperactivity, stereotyped pacing before feeding time and stereotyped over-drinking and pecking at non-food objects after feeding.

Hunger appears to increase locomotor activity in many animals, including laboratory rats, and it is theorized that in the wild such a response may increase the animal's chance of finding food. Offspring of many animal species (including birds, mammals and insects) signal their nutritional needs (hunger level) to the parents by conspicuous vocal, visual or tactile begging displays. Cold and hungry piglets removed from the sow and placed in isolation vocalize more than control piglets, while calves vocalize significantly more in response to milk deprivation. Increased gaa-calling (a vocalization widely believed to express **frustration**) from hens occurs with an increasing hunger state (in addition to increased pacing and displacement preening).

Hunting

Hunting is the chasing of an animal, usually with the intention of killing it. The reasons are various but include hunting an animal for its pelt (e.g. seal), for food (e.g. wild birds), population control (e.g. rabbits), to conserve a flock or herd (e.g. deer control) or other industries (e.g. seal hunts to protect fishing, rabbits for crop protection), for prestige (e.g. when killing the 'big five' game animals (African lion, elephant, buffalo, rhinoceros and leopard) and for 'sport'. Hunting may be carried out with dogs (e.g. hunting foxes, game birds where the dogs according to breed may point, set up, retrieve), by trapping (e.g. for pelts) or stalking (deer, the 'big five'). Killing the hunted animal usually involves the use of guns, but may also involve crossbows or other physical methods, or with some prey the dogs may kill the hunted animal.

Hyperalgesia

Hyperalgesia refers to a state of increased sensitivity to pain and may arise as a result of either local neural changes (e.g. damage to sensory nerves) or systemic factors (e.g. following cytokine production in response to disease). Hyperalgesia also refers to an increased area of pain, and is caused by a phenomenon of 'wind-up' of neuron(s) in the dorsal horn of the spinal cord. Hyperalgesia differs from allodynia in so much as a painful stimulus is required to determine the former, unlike the latter, which may be triggered by nonpainful touch.

(DSM)

Hypothalamic-pituitary-adrenal (HPA) axis

The hypothalamic-pituitary-adrenal (HPA) axis refers to an organ system comprising the **hypothalamus**, the **pituitary gland** and the **adrenal gland**. The hypothalamus is an organ formed of many separate nuclei and lies in the **central nervous system** below the thalamus. The pituitary gland lies below the hypothalamus and the two are connected by a tract of **neuron(e)s** called the hypophyseal stalk. The adrenal glands are a pair of endocrine glands that are located beside the kidneys; they are comprised of a medulla and a cortex. The term 'axis' refers to the fact that these three organs are able to control one another by stimulating production of hormones, as well as by terminating the production of hormones.

The HPA axis has been the main focus of much research on the **stress** response; however, it is important to remember that the HPA axis is always active, and thus quantifiable measurement of any of its components does not indicate a definitive stress response. The function of the HPA axis is to help maintain **homeostasis** by regulating glucose availability. When an animal is challenged with a **stressor**, activation of the HPA axis is heightened and thus its products can serve as a physiological indicator of stress in animals. When a stressor is perceived, sensory input from the thalamus activates neurons in the paraventricular nuclei of the hypothalamus to release **corticotropin-releasing hormone (CRH)**.

The axons of these nuclei terminate in the hypophyseal portal vessels, which bathe both the hypothalamus and the pituitary gland. Thus hormones entering this portal system allow communication between the two organs. Once in the portal blood, CRH binds to receptors on the plasma membrane of corticotroph cells in the anterior pituitary gland. Activation of this receptor causes the corticotroph cells to secrete adrenocorticotrophic hormone (ACTH) and β -lipotropin into the peripheral vasculature. Binding of CRH to its receptor also causes the corticotroph cell to produce proopiomelanocortin (POMC), the precursor to several hormones including ACTH and β -lipotropin. Once in the blood, ACTH reaching the cortex of the adrenal gland binds to its plasma membrane receptor on cells in the *zona fasciculata* and the *zona reticularis*, two of three cell layers in the adrenal cortex. Activation of its receptor causes the production and release of **glucocorticoids** into the peripheral circulation.

In livestock, cortisol is the glucocorticoid that is produced in greater quantities, whereas in rodents and birds corticosterone is produced in greater quantities. Glucocorticoids in the blood are then bound to protein carriers which help to transport them and decrease their degradation. **Corticosteroid-binding globulin** binds cortisol and, to a smaller extent, cortisol is also bound by albumin. A certain percentage of the hormone remains unbound and it is this portion that is able to bind to its receptors in target tissue to cause an increase in glucose and free fatty acids. Free circulating glucocorticoid is able to feed back negatively on both the hypothalamus and the pituitary gland to decrease further production of cortisol or corticosterone. By binding to receptors in the paraventricular nucleus, cortisol decreases the production of CRH and, by binding directly to the corticotrophs in the anterior pituitary gland, ACTH production is decreased, thus decreasing the production and secretion of glucocorticoids.

One characteristic of the HPA axis that has made it useful in the determination of chronic stress in animals is that under chronic stress the cells of the *zona fasciculata* and *zona reticularis* in the adrenal gland will undergo hyperplasia and hypertrophy. This occurs in response to the heightened and constant stimulation of the adrenal gland by ACTH from the pituitary gland. In the cadaver, researchers can collect the adrenal gland

P.332

and look for size, weight and morphological differences to determine whether they have been subjected to chronic stress. Similarly, in the live animal, researchers can administer ACTH to the subject and measure the resultant concentrations of glucocorticoid to determine whether the adrenal gland is more capable of producing cortisol or corticosterone. If so, this would indicate that the animal has been exposed to a significant amount of stress to cause its adrenal glands to enlarge, although in some circumstances the gland may become hypo-responsive and produce a below-normal response.

Challenges to using circulating levels of glucocorticoids in the measurement of stress deal with hormone dynamics and varied causes for its elevated concentrations in the body fluids. Dependent upon the assay system used, glucocorticoids can be measured as total, bound or free concentrations. It is only the free concentrations that are available to the animal's body to use; however, the bound portion represents a pool of readily available hormone. Thus, measuring total hormone versus free hormone will present a different view of the welfare status of the animal. Another challenge is that glucocorticoids can be elevated in situations that are not thought to be aversively stressful to an animal. For example, glucocorticoids have been shown to be elevated in animals during copulation, play and exercise. Objective measurement of stress in animals requires a multidisciplinary approach to increase the confidence in asserting when an animal is stressed and its welfare diminished.

(DCL)

Hypothalamus

The hypothalamus is the part of the brain that is located below the thalamus and above the brain stem, forming the ventral part of the diencephalon (**see: Central nervous system**). Among other functions it provides a link between the nervous system and the endocrine system via the **pituitary gland**. The hypothalamus influences activity within the **autonomic nervous system** and is responsible for synthesizing and secreting neurohormones (hypothalamic-releasing hormones - **corticotropin-releasing hormone (CRH)**, **gonadotropin-releasing hormone (GnRH)**, **growth hormone-releasing hormone (GH-RH)**, growth hormoneinhibiting hormone (GH-IH), prolactin-releasing hormone (PRH), prolactin-releasing inhibiting hormone (PRIH), thyroid-releasing hormone (TRH)), which either inhibit or stimulate the secretion from the pituitary gland of other hormones. The hypothalamus also plays an important role in regulating body temperature (**see: Thermoregulation**), hunger, thirst (**see: Drinking behaviour**) and circadian rhythms.

IACUC stands for the Institutional Animal Care and Use Committee and is a requirement under US federal law for all institutions that use **laboratory animals**. The committee's role is to oversee and evaluate the institution's animal care policy and use of animals.

(DSM)

Ideal free distribution (IFD)

The ideal free distribution (IFD) is a model of how animals distribute themselves between patches/habitats in relation to resource availability. The model assumes that animals behave in a way that optimizes some aspect of their day-to-day behaviour (usually foraging). The model also assumes that animals have ideal knowledge about resource availability and are free to move between patches (e.g. they are not prevented from accessing a resource by despotic competitors). A key prediction of the IFD is the resource-matching rule: essentially, animals will distribute themselves in proportion to resource availability. For example, should patch A contain twice the amount of resource of patch B, twice as many animals will settle in patch A than in patch B.

(PE)

Imitation

In everyday language, the word imitation is used to describe any instance of copying the behaviour of others. However, within the field of animal behaviour, imitation refers to a very specific method of learning. Imitation takes place when one individual observes another (typically a **conspecific**) and reproduces a relatively faithful copy of their behaviour, including both their actions and the results caused by those actions. Imitation is one of several methods of learning collectively known as **social learning**. Social learning incorporates all learning that is influenced by the behaviour of others, and is distinct from individual learning (such as trial and error), which is not affected by others. Learning from others can be advantageous because it allows new behaviours to be learned faster, and with less potential risk than trial and error. For example, a young bird may learn which trees contain edible - rather than poisonous - berries by learning where other birds feed. The bird therefore saves energy and reduces risk because it does not have to fly to every tree and sample every berry.

Social learning includes all methods of learning that result from either interacting directly with another, from observing the behaviour of another or even from interacting with the left-over products of another individual's behaviour. For instance, black rats (*Rattus rattus*) can learn to efficiently extract seeds from pine cones if they are simply given pine cones that have already been opened by another rat. Put simply, all methods of social learning are influenced in some way by the behaviour of others.

Historically, imitation was viewed as a relatively simple form of learning that was widespread among animal species. However, recent studies suggest that imitation is a cognitively complex process (see

below) that is not as prevalent as once thought. In humans, imitation is thought to play a fundamental role in language acquisition, learning about objects, acquiring cultural behaviours as well as identifying with, and understanding, the minds of others (**theory of mind**). For this reason many researchers have focused on studying which non-human species have the capacity to imitate.

In order to identify imitation, it must first be distinguished from a variety of other methods of social learning, such as **goal emulation** or **local enhancement**. Each method differs in how faithfully an observer reproduces the behaviour of another (the model). However, imitation is the only form of social learning whereby an observer learns to reproduce the model's actions in addition to the results of those actions. Hence imitation results in the highest fidelity match to the model's original behaviour, and can be identified by copying actions and results.

Imitation can be investigated using a 'two-action' paradigm. Two-action paradigms involve a task that can be solved by using one of two different actions (A or B). One example is an 'artificial fruit' that has been used to show that **chimpanzees** (*Pan troglodytes*) can imitate (see Fig. 1.1). This artificial fruit is a box containing food. The lid of the box is held closed by two bolts that must be removed before the lid can be opened. The

P.334

bolts can be removed by either pushing them (action A), or pulling them (action B) out of their holders (see Fig. 1.2). To test for imitation, chimpanzees are divided into two groups. One group observes a model pull the bolts out to open the lid, while the second group observes a model push the bolts out. Observers from each group are then given an opportunity to open the box on their own. If each group uses the same action as their respective model (push or pull) significantly more than the alternative to achieve the same result (open box), this indicates imitation. Two-action paradigms provide a particularly useful tool for studying imitation because they can be adapted for use with a wide range of species.

Fig. I.1. Photograph of a chimpanzee pulling the bolts out of the 'artificial fruit' in order to open the lid and retrieve a food reward. Photograph reproduced with kind permission from A. Whiten.

There are, however, disagreements about the details of how two-action tests are conducted. Some argue that simply copying the same action (pull or push) is not enough observers must use the same body part as the model to perform the action. For example, marmosets (*Callithrix jacchus*) that observed a demonstrator use their mouth to remove the lid of a food container also used their mouth when opening the container themselves. Marmosets that observed a model remove the lid with their hands used their hands instead. There are further debates about how novel the two alternative actions must be, and about whether or not an observer must understand the intentions of the model. Nevertheless, despite these questions, the two-action paradigm is generally accepted as the standard way to test for imitation.

Fig. 1.2. Schematic representation of the two alternative actions used to open the 'artificial fruit' two-action paradigm used to demonstrate imitation in chimpanzees: (a) pull bolts out to open lid and retrieve food; or (b) push bolts out.

Imitation is typically studied in captivity because controlled experimental conditions are necessary for two-action tests (**see: Laboratory study**). Such studies have revealed that imitation can be affected by the relationship between the model and the observer. Observers are less likely to imitate models that are aggressive towards them than those that are tolerant of being observed. Hence imitation, and social learning in general, may be more prevalent in tolerant than despotic animal societies. Similarly, evidence for imitation may be affected by the difficulty of the task. If a problem is too easy, an individual may not need to imitate because they can solve the task on their own. Hence it has been suggested that the strongest evidence for imitation comes from reproduction of arbitrary actions, rather than from solving puzzles. Chimpanzees and **orang-utans** (*Pongo pygmaeus*) taught to copy human actions on command (like the game 'Simon says') were able to imitate completely novel gestures.

Imitation is believed to be cognitively complex because an observed behaviour (visual input) is converted into action (motor output). Several theoretical frameworks have been proposed to explain this process, the best known being the 'active intermodal mapping' hypothesis, which suggests that

P.335

imitation is possible because an individual can determine when its own body movements match observed actions via a perceptual feedback system. Such hypotheses are supported by the recent discovery of specialized **neuron(e)s** in the inferior frontal lobe of primates, known as mirror neurons, which appear to

be specialized for behaviour matching. These neurons are thought to be involved in imitation because they have both sensory and motor functions, and are activated when an individual performs a behaviour (such as reaching for an object) as well as when observing the same behaviour performed by another. Further studies will be needed to determine whether similar neurons exist in non-primate species.

Vocal imitation has typically been treated separately from action imitation because it is thought to involve different cognitive pathways that match auditory and vocal domains rather than visual and motor domains. The debate over the relationship between vocal and action imitation remains unresolved.

Immune system

The primary functions of the immune system are, first, to prevent disease by preventing pathogen entry and colonization and, secondly, to clear ongoing infections. The immune system is not a static system. It is now believed that a healthy immune system is one that has been exposed to antigens throughout development, thereby developing an adequate education of self and non-self and immunological memory. Some aspects of the immune system are well conserved among species, but occasional pronounced differences can be observed. This article will focus on general immunology, with some reference to species-specific differences.

The six common classes of internal disease-causing organisms are: viruses, bacteria, fungi, protozoa, nematodes and helminths (the latter two are varieties of worm). The latter three constitute the discipline of parasitology and the first three are within the discipline of microbiology. The efficiency of the immune response is relative to the disease with which it is being challenged, and the immune system is arbitrarily divided into two systems, innate immunity and adaptive immunity. Some disease challenges are controlled best by an innate immune response, while others are controlled best by adaptive immunity. Adaptive

immunity requires prior exposure to antigen, while innate does not. However, these two systems are closely connected, and are derived from the same cell source.

The cells of the immune system originate from the bone marrow. Myeloid progenitor cells are the precursors for monocytes, dendritic cells, mast cells and granulocytes. Lymphocytes (derived from lymphoid progenitor cells) mature in the bone marrow or the thymus (see Table I.1).

Monocytes in the blood mature into macrophages as they migrate into the tissues. Some become specific and are named to reflect the tissue in which they reside; macrophages in the liver are Kupffer cells, while those residing in the brain are termed microglial cells, and those residing in the kidney are intraglomerular mesangial phagocytes. Those residing in the lungs are simply termed alveolar macrophages. Macrophages serve multiple roles. They are crucial in both innate and adaptive immunity.

Dendritic cells are highly specialized in their role in recognizing and presenting antigen to lymphocytes in the lymph tissues. Immature dendritic cells travel from the blood into tissues, where they continually sample the environment. Once they encounter a pathogen, they quickly mature and migrate to lymph nodes.

Mast cells are bloodborne, but differentiate as they move into tissue. They primarily reside near small blood vessels and, when activated (through immunoglobulin E cross-linking), secrete substances that cause vascular permeability. They are renowned for this role during allergic responses.

The granulocyte population is also known as polymorphonuclear (PMN) leucocytes, having a distinctive, multisegmented nucleus. These cells are full of densely staining, granule-containing lysosomes, which are used for bactericidal activity. Neutrophils, eosinophils and basophils are members of the granulocyte population. Neutrophils are possibly the most important cells of innate immunity. Hereditary deficiencies of neutrophils lead to fatal bacterial infections. They are the third phagocytic cell of the immune system (besides macrophages and dendritic cells), but function only in innate immunity. In birds, analogous cells are called heterophils. Eosinophils have dual roles; they are believed to be important during parasitic infections because of observed increasing numbers. However, they also play a role in allergic responses. Basophils function similarly to mast cells and eosinophils, with their primary role in allergic responses.

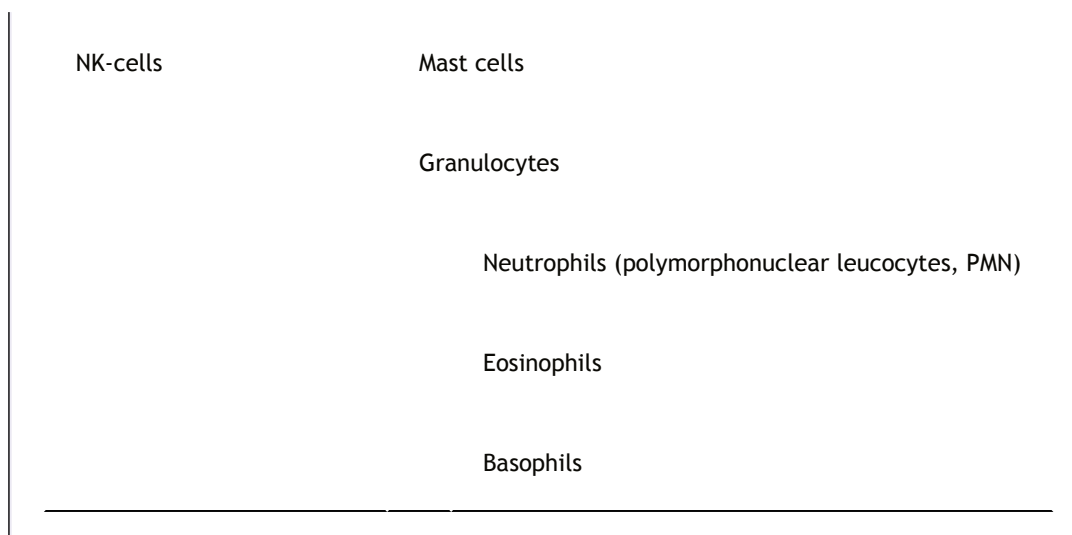

Lymphocytes originate from bone marrow. There are two major types of lymphocytes: B-lymphocytes (B-cells), which differentiate into antibody-producing plasma cells when they are activated, and T-lymphocytes (T-cells), which can be

P.336

divided into two classes - one is the cytotoxic T-cell and the other is the helper T-cell, which activates other cells such as the B-cell and macrophages. Lymphocytes mature in the bone marrow or the thymus.

Table I.1. Cells of the immune system.

Lymphoid progenitor cells	Myeloid progenitor cells
B-cells	Monocytes/macrophages
T-cells ($\alpha\beta$ and $\gamma\delta$)	Dendritic cells

Primary (or central) lymphoid organs, where lymphocytes are generated, are the bone marrow and thymus. B- and T-lymphocytes originate from the bone marrow, but only the former mature there. T-lymphocytes migrate to the thymus, where they mature and develop the ability to discriminate self from non-self. The secondary lymphoid organs, which are widely distributed throughout the body, are where adaptive immune responses are initiated and where lymphocytes are maintained. It is to the secondary lymphoid organs that dendritic cells and macrophages carry their antigens to present to B- and T-cells to start an immune response. The secondary lymphoid organs include lymph nodes, the spleen and gut-associated lymphoid tissues (GALT). Included in GALT are the tonsils, adenoids, the appendix and specialized structures in the small intestine called Peyer's patches.

Leucocytes move among the tissues and organs and through the lymphatic and circulatory systems. Chemotaxis to a site of inflammation is initiated by chemokines (**see also: Cytokines**) and by peptides produced by neutrophils. Adhesion molecules on the cell and integrins on the endothelial surface become more tightly bound as the concentration of the chemoattractant increases. This leads to what is termed rolling and, eventually, diapedesis (movement of the cell through the blood vessel by squeezing between endothelial cells).

Innate immune response

The immune system begins with physical barriers. Skin and mucosal surfaces serve to keep pathogens at bay. The respiratory tract, gastrointestinal tract and urogenital system comprise the mucosal immune interface. The mucosal immune system is where the host most frequently encounters pathogens. Mucosal immunity must not only recognize pathogens, but it must also be capable of discriminating commensal microbial populations. Within the mucosa are immune cells that interact immediately with pathogens. Multi-fenestrated cells (M-cells) 'sample' the lumen of the gastrointestinal tract and interact with subepithelial lymphocytes and dendritic cells. The dendritic cells take the antigen to lymph tissues. Gamma-delta ($\gamma\delta$) T-cells are a subset of lymphocytes that are prolific in the gut mucosa. This subset of cells varies in phenotypic markers, predominant location within the body, abundance and function among species and age of animal within species, but generally has an innate immune function, requiring no previous experience with the antigen.

Cells of the innate immune system recognize foreign antigen without prior exposure and can trigger an appropriate immune response. Subsets of the innate lymphocyte population include the $\gamma\delta$ T-cell and natural killer (NK-) cells. Both the NK-cells and $\gamma\delta$ cells are phenotypically and functionally different among species. For instance, NK-cells are a prominent and important innate immune cell in humans and pigs, but appear to be inefficient at lysing tumour cells unless they have been activated by cytokine in

cattle. However, they still appear to be efficient at lysing virally infected cells. Additionally, the bovine NK-cells are phenotypically distinct from NK-cells of other species. $\gamma\delta$ cells comprise a large proportion of circulating lymphocytes, up to 30% of peripheral blood mononuclear cells (PBMC) and afferent lymph cell populations, and there is typically a greater percentage of PBMC in young calves than in mature cattle. In contrast, young piglets have only 3% $\gamma\delta$ cell population in the blood, but greater percentages in the GALT. NK-cell activity is developed postnatally in pigs as opposed to prenatally in many other species, so the neutrophil is a very important innate immune cell in the neonatal piglet.

Neutrophils are phagocytic cells that ingest and kill foreign antigen without prior exposure (see Fig. 1.3). Particles that have become opsonized (coated with antigen-specific antibody) are ingested much more efficiently. Neutrophils are a predominant source of antimicrobial peptides. These are peptides produced by neutrophils that use several mechanisms, to either destroy microbes or inhibit their replication through molecular intervention.

Convergence of innate and adaptive immune systems

Macrophages and dendritic cells are two important phagocytic and antigen-presenting cells. They interact with T-cells to initiate an immune response that will lead to cytotoxic T-cell activity or to antigen production. This interaction occurs at the T-cell receptor. A 'self' signal, termed major histocompatibility complex (MHC), is generated by the macrophage

P.337

and presented on the cell surface with the antigenic peptide and is required for this signal to be complete (see Fig. 1.4).

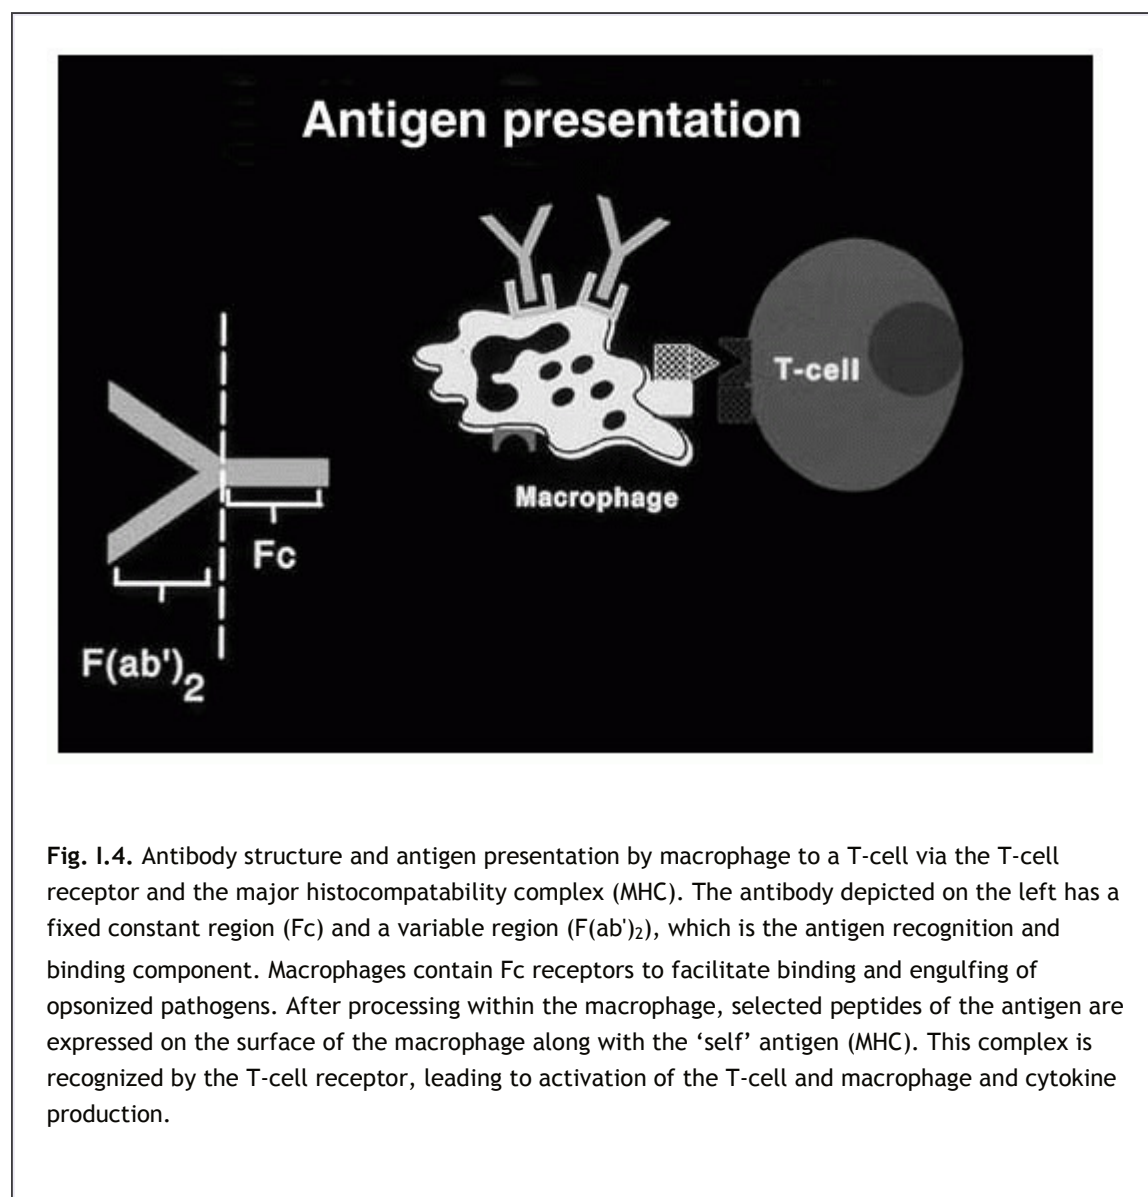

Fig. 1.3. The phagocytosis process by neutrophils begins with attachment of the neutrophil, sometimes mediated by binding of the fixed constant (Fc) region of the antibody to the Fc receptor on the neutrophil. Phagocytosis ensues, with the phagocyte membrane surrounding the pathogen. The vesicle of the bound pathogen is called a phagosome. Lysosomes (vesicles containing enzymes, proteins, peptides and oxygen and nitrite intermediaries) fuse with the phagosome, creating a phagolysosome where the pathogen is destroyed by an oxidative burst.

Macrophages are frequently the first cells to encounter pathogens. Macrophages carry their cargo to lymph nodes for presentation to T-cells. They release a number of cytokines and chemokines that initiate an appropriate immune response and recruitment of accessory cells. The receptors that signal the presence of pathogens also upregulate co-stimulatory molecules on both macrophages and dendritic cells, leading to the adaptive immune response. Macrophage interaction with T-cells leads to cell signals and cytokine production (Interferon (IFN)- γ) that activates the macrophage to become bactericidal through nitric oxide, oxygen radical and proteases. As could be expected, this process can be destructive to

surrounding tissue, and is therefore tightly controlled by the encoding of mRNA for IFN- γ with a sequence that reduces IFN- γ 's half-life.

Macrophages and dendritic cells differ in initial location, in trafficking throughout the body and by the type of cytokine that they produce. Langerhans cells are dendritic cell precursors found in the skin. Immature dendritic cells have a different appearance than those that are activated and have begun translocation to the secondary lymph tissues. The immature dendritic cell has low MHC protein expression and lacks co-stimulatory molecules necessary to interact with T-cells. In transit to lymph tissues, they stop phagocytizing antigen and their morphology changes. The lysosomal proteins and MHC class II molecules become distinctly separate. In the lymph nodes, dendritic cells express high levels of MHC-peptide complexes and co-stimulatory molecules. It is here that the innate and adaptive immune systems converge.

Dendritic cells reside in T-cell areas and are potent stimulators of naive T-cells. Both dendritic cells and macrophages express toll-like receptors (TLRs) (pattern recognition molecules) that discriminate pathogen

-associated molecular patterns (PAMPs) of various pathogens. TLRs are expressed on the cell surface. Each receptor or heterodimer recognizes discrete PAMPs (see Fig. 1.5).

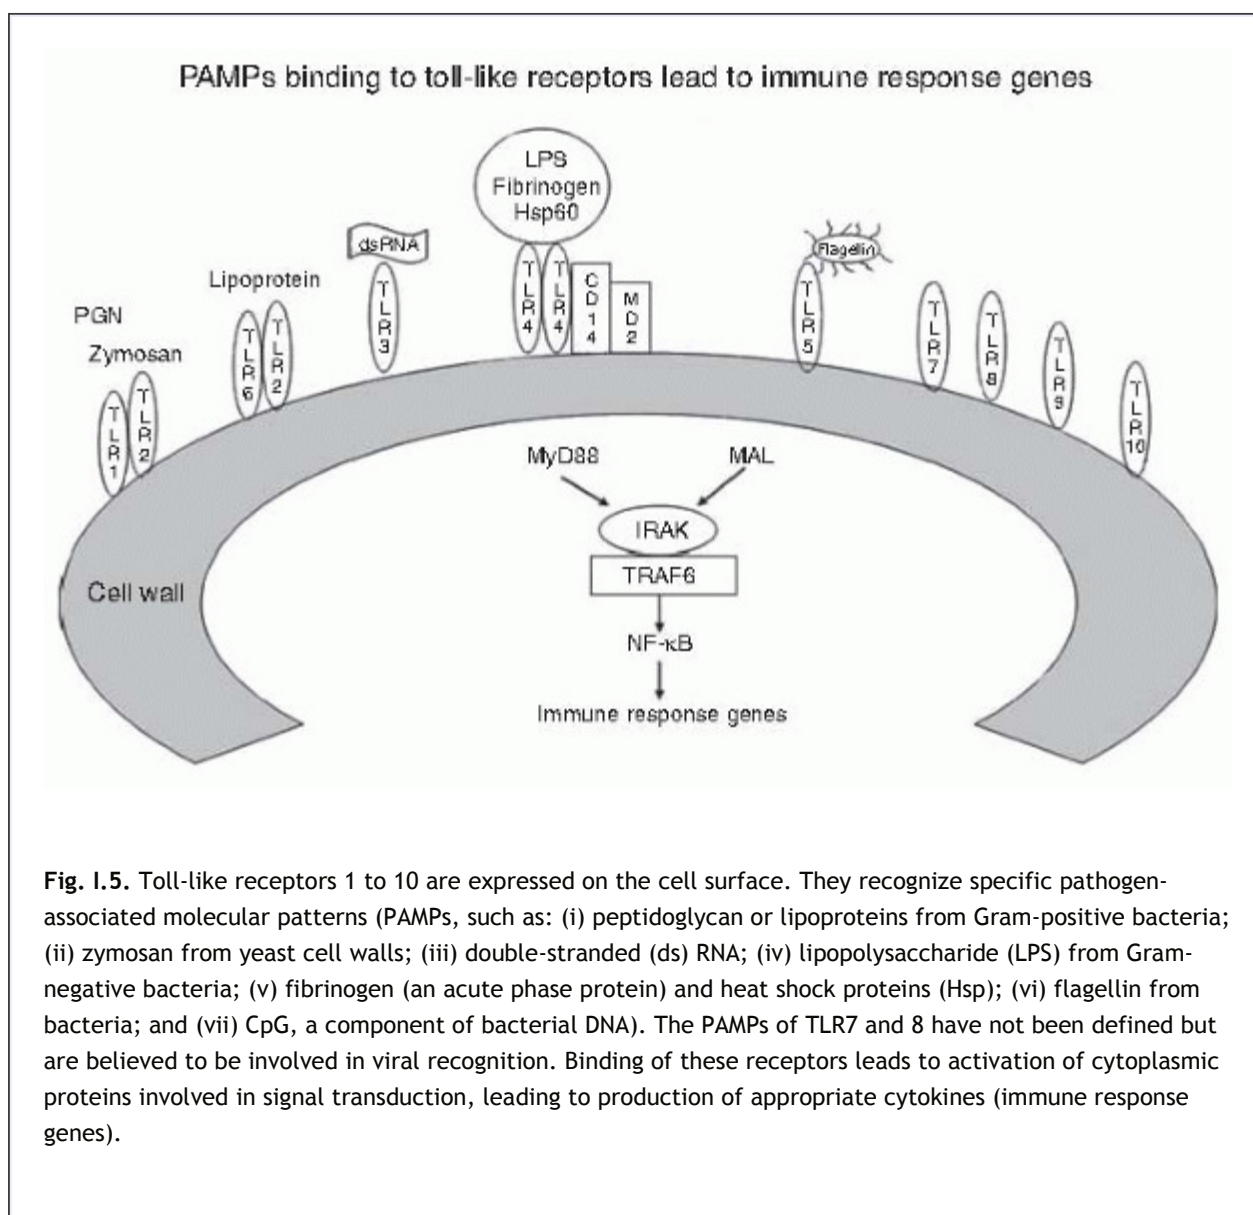

Although the exact agonist of TLR7 and TLR8 has not been identified, these receptors have been shown to mediate activation of antiviral immunity. Following stimulation of the TLRs, a cascade of signals begins leading to the production of inflammatory cytokines, such as TNF- α and IL-6, and upregulation of the co-stimulatory molecules CD80 and CD86 on dendritic cells. Several accessory molecules have been identified that are required for cell activation - MD2 and CD 14, which associate with TLR4, and the cytoplasmic factor MyD88, which mediates binding to intracellular domains. A second co-factor, TIRAP (also called MAL), is essential for MyD88 to mediate induction of an important cell signal.

TLRs play a vital role in the adaptive immune response; they are necessary for priming TH1 and TH2. Signalling through TLR4 has been demonstrated to induce both TH1 and TH2 responses, depending on the dose of LPS used. The lower expression of TLR1 was correlated with low antibody responders compared with normal responders following vaccination with *Borrelia burgdorferi* (the causative agent of Lyme disease).

Once macrophages have been activated by TLRs, the pathogen is internalized and the peptides are expressed on the cell surface in conjunction with MHC I or II, depending on the type of antigen that is being presented. Virus particles are presented with MHC class I molecules and bacterial particles are presented with MHC class II. T-cells express receptors specific for the MHC and antigen. Cytotoxic lymphocytes (CD8+) interact with MHC class I-expressing macrophages. These cells produce cytokines and enzymes for efficient cellkilling activity. Conversely, T-cells with a receptor specific for the antigen and the MHC class II antigen secrete cytokines that enable antibody production and clearance of the organism by those routes. These include both the TH1 and the TH2 subsets. It is at this point that the type of cytokines present in the milieu can affect the type of effector T-cell that is generated.

In the lymph node, dendritic cells that have encountered viruses and some bacteria induce NK-cells to produce IFN- γ by IL-12 production. This results in a CD4+ T-cell that secretes IL-1, TNF- β and IFN- γ . With other stimuli such as parasites, the NK-cells produce IL-4 and the dendritic cells are not stimulated to produce IL-12. This scenario results in a CD4+ cell that produces IL-4, IL-5 and IL-13. Each of these subsets produces cytokines that act negatively on the opposite subset. To complicate the issue, the differentiation of CD4+ subsets is influenced by the amount, affinity and avidity of the peptide. CD4 T-cells presented with low levels of a poorly binding ligand will differentiate preferentially into TH2 cells that produce IL-4 and IL-5. This makes them most effective in stimulating naive B-cells to differentiate into plasma cells and making antibody. In contrast, T-cells presented with high levels of ligand with strong binding to the T-cell receptor secrete IL-2, TNF- β and IFN- γ and are effective in activating macrophages.

P.338

Adaptive immunity

The antibody is composed of a fixed region that is recognized by phagocytes (see Fig. 1.4.) and a variable region that is flexible and conforms to hold the antigen peptide. Five isotypes of antibody are recognized, including immunoglobulin D (IgD), IgA, IgG, IgM and IgE. Subclasses of IgG vary by species, but four are recognized in humans. Additionally, while the major isotype classes are consistent among species for function, the subclasses are not. Very little immunoglobulin D is produced at any time. B-cells express both IgD and IgM on their surface. Immunoglobulin A and M form polymers that are unique to their functions. The repetitive binding site of IgM increases its avidity (ability to remain bound to the antigen), possibly because of its weaker affinity (strength of the binding) for each of those sites. IgE is in very low concentrations, but is responsible for tight binding to mast cells that can trigger the release of chemicals that cause sneezing, coughing and vomiting. IgA is the predominant form of antibody contained in colostrum and therefore passive immunity; however, IgG is also transported and plays a vital role. Polymerization of IgA is necessary for its transport through epithelia. IgG is the predominant circulating isotype that is involved in the presentation of antigen to phagocytes.

Passive immunity is the transfer of antibody from a maternal source to either a **fetus** or neonate. Antibody transfer in humans is through the placenta; however, many farm animals receive maternal antibodies through colostrum. Colostrum is the initial lactation secretion produced after **parturition**. It is high in energy, nutrients and antibodies compared with milk secretions that ensue within the first week of lactation. The neonate has a small window of opportunity for optimum antibody absorption: the ability to absorb the antibodies begins to decline as early as 12 h after birth. After 24 h the colostrum can continue to have a limited protective effect by interactions with pathogens within the lumen of the gastrointestinal tract.

There are three functions of antibodies. The first is neutralization. Many bacteria injure cells by secreting toxins. The neutralization function of antibodies is to recognize and keep the toxin from binding to cells. The second function is action by opsonization. This is the coating of an antigen with antibodies or complement. The Fc portion of the antibody is then bound by phagocytes, such as neutrophils, and the antigen ingested and killed. The third function of antibodies is through activation of plasma proteins known as complement.

Complement is a unique system that not only functions as an effector arm for antibodies, but can also act independently with activation early in infection. It comprises a number of plasma proteins that work in a triggered-cascade system. There are three distinct pathways for complement activation. Complement works to provide its protective effects through: (i) covalent binding to pathogens, allowing them to be engulfed by phagocytes; (ii) some of the smaller, cleaved components from the cascade acting as chemoattractants for phagocytes and inducing activation; and (iii) the terminal complement component damaging the cell walls of bacterial membranes by creating pores.

The immune system is a complex system, but with a relatively small number of types of cells involved. It begins with basic innate immune responses, these eventually leading to interaction with cells of the adaptive immune system. Through these interactions of cells, cytokines and proteins, immunity is developed against specific antigens. Finally, memory cells are left that can mount a rapid antibody response if the antigen is encountered again.

Imprint training

While **imprinting** refers to the learning process whereby a neonate may follow the first moving object it sees during a **critical period** of development, its relevance to **horses** is less clear. In the past 20 years or so, the term imprinting or imprint training has been extended to represent an equine training protocol conceived by Robert Miller. Miller (1991) claimed initially that the neonatal foal was subject to a similar critical period and that this facilitated a range of related training exercises. He subsequently acknowledged that the training process is not related to the imprinting process, and recent work suggests that the foal may learn from the response of the mother to people during handling (Henry *et al.*, 2003).

As a **precocial** neonate, the newborn foal must get to its feet as rapidly as possible and be capable of fleeing from predators and learning all the concomitant behaviours necessary for escape and the features of their world that are not threatening. So, it seems reasonable to train the newborn foal to react appropriately and at a time in its life when there is a lower chance of injury to both horse and human as a result of a **flight behaviour** response.

Miller's programme involves serial **habituation** of the foal, followed by training distinct cues that elicit specific responses. The foal's body is manipulated by the handler, a process Miller describes as 'stimulations'. He prescribes multiple (30 to 50) stimulations of each body area. Imprinting begins with the handler drying the newborn foal. Handling starts at the foal's head and continues in a preset pattern all over the body, moving from one area to the next when the foal relaxes (habituates). All areas of the body are covered, including ear canal, nostrils, mouth, perineum and external genitalia.

The next phase involves introducing various devices, such as clippers and a rectal thermometer. The imprinting programme continues with the introduction of head collars, and a desensitization process in which the foal is accustomed to crackling plastic (again, until it shows no fear), gunshots, loud music and many other potentially aversive stimuli. On the following day the foal, adjacent to its dam, is re-exposed to the desensitization process, but this time for no more than 15 min. The next stage involves restraint, where the handler's arms envelop the foal's thorax, squeezing rhythmically until habituation occurs.

The merits of these exhaustive interventions have been questioned by recent studies of early equine handling. The existence of a discrete early critical period in horses has been challenged (Williams *et al.*, 2003). Equine ethologists have suggested that a training window may exist around **weaning** time, which is usually at approximately 6 months of age, when the animal is in a state of continual heightened **arousal**. This state offers the potential for rapid learning (Bateson, 1979).

There are potential risks in handling neonatal foals, since the mare-foal relationship could be damaged, the handler could be injured by an aggressive or protective mare, foals may be injured if they struggle and, later in life, the 'imprinted' animals might present a danger to humans because they become targets for play or **sexual behaviour**. Imprinting of horses remains an area in which more research is needed. While it seems clear that Miller was wrong in his initial claim that his regime was a form of imprinting, there may be some justification for some limited early intervention.

Imprinting

Imprinting refers to the ontological learning process whereby an animal identifies an object (**see: Bonding - parent/offspring**) and subsequently follows and responds to it in preference to other stimuli. In **precocial** birds, such as chickens, ducks and geese, imprinting is largely a response to visual stimuli, so the first moving object seen during the so-called '**critical period**' (between 26 and 32 h of age) is imprinted and followed throughout the juvenile period. Furthermore, when the imprinted bird is sexually mature, it will attempt to mate with objects similar to the one it imprinted upon (Immelmann, 1972). This learning, first identified by **Konrad Lorenz**, is virtually irreversible so, clearly, imprinting has evolved to promote survival of newborn animals and to shape their future **reproductive behaviours**. Sound and **olfaction** are also involved in imprinting, with the importance of each sense depending on the species.

Knowledge gained through imprinting is retained for life and difficult to reverse. It establishes an individual animal's preference for a certain species. An inappropriately imprinted neonate will prefer to follow the learned stimulus (such as a human or even a balloon or a stick) rather than a member of its own species.

Not all behaviours are affected by imprinting. In sexually dimorphic species, imprinting of mate choice is sex specific. A male chicken will search for attributes in a mate that are similar to those of his mother, whereas a female will not. Interestingly, sexual responses in human-imprinted falcons are evoked only with a combination of human and avian stimuli.

Imprinting seems more important in precocial species, in which the offspring are less dependent on their mothers for food and warmth, than in **altricial** species, which keep their

P.340

vulnerable, and often nude, young in nests or burrows. Altricial neonates are unlikely or unable to stray from their refuges in the first few days of life, so imprinting is unnecessary. Instead, they learn similar lessons later in life during what are known as '**socialization periods**'. Once the animal's sensory, motor and thermoregulatory systems are functional, they learn to move away from their mother and interact with **conspecifics** and other species. The socialization period varies according to the species. In dogs it is from 3 to 14 weeks and in cats 2 to 7 weeks, while in primates it is usually 6 to 12 months. Stimuli that the youngsters of each species are exposed to during these periods will be accepted as 'normal'.

Aversive experiences during imprinting create a more robust imprinting response than usual. When obstacles are placed in the runway between a duckling and the imprinted object, the following response

is more energetic and determined. It is likely that this feature of imprinting is an adaptive anti-predator response.

Inbreeding

Inbreeding is often used to describe the mating of closely related organisms. The result is that offspring tend to be homozygous, i.e. to have inherited copies of the same gene from each parent. Thus, it has been used by animal breeders to fix desirable inherited characteristics in breeds, i.e. for making a breed of domesticated animals uniform in appearance or performance. An inbred animal is one that has inherited from both parents copies of a piece of DNA belonging to an ancestor that is in the pedigree of both parents. The inbreeding coefficient is a measure of how likely it is that a particular pair of alleles is identical to that of an ancestor - put another way, it is the proportion of the gene pairs of an individual that are identical.

It is usually a disadvantage for organisms to have inherited identical copies in this way, in other words to be homozygous - if the gene is defective the organism will be at a disadvantage. If the organism has received a different copy from each parent, it will be heterozygous and, if one of the gene pair is defective, this will often be masked by the other, functional, one.

Homozygosity means that an organism is genetically less well equipped to deal with varying circumstances. This need not be a problem with **farmed animals**, where the art of husbandry is to remove environmental constraints on growth and production. But in the wild, homozygous organisms tend to be less viable than non-inbred (outbred) individuals and, as would be predicted, many species have evolved mechanisms to restrict inbreeding. To do this, animals must be able to recognize their relatives. The mechanism that is currently the strongest candidate as an indicator of relatedness is based on the set of genes known as the major histocompatibility complex (MHC). Laboratory mice clearly prefer to mate with individuals whose MHC type differs from their own (Brennan and Zufall, 2006), and there is some evidence (based on tests of preferred body odours) that humans do likewise. Female fur seals also move across a breeding colony to locate males that are more distantly related (Hoffman *et al.*, 2007).

If populations are inbred for many generations, the probability of extinction is high (Falconer and Mackay, 1996), but populations that do manage to survive may, as a result, have been purged of harmful recessive alleles (Visscher *et al.*, 2001). However, enough breeds have been inbred over time and still retain harmful recessive genes (this is particularly evident in dogs) to mean this is not a valid general strategy.

Inbreeding therefore poses a particular problem if there are many defective genes in a population. If the genes are only slightly defective then the result may be a relatively minor decrease in performance; the same is true if many genes code for a trait, as only a proportion of them will be present as identical gene pairs. For example, detailed milk records of thousands of cows whose pedigrees are known show that a 1% increase in inbreeding of dairy cows leads to a decrease of 6 days in total productive life, a reduced lifetime production of 177 kg of milk and an increase of 0.6 days in age at first calving. This is not life threatening but, if there are genes present in the population that would definitely be harmful when homozygous, inbreeding can lead to serious health and welfare problems, or even to mortality.

With all populations some degree of inbreeding is inevitable, but domesticated animals are in general not adversely affected provided it is not too intense, and occasional outbreeding (use of animals from a different breed or from a segment of the breed that has been kept relatively separate) will usually rectify harmful effects that are coming apparent.

As inbreeding leads to less adaptable animals, there is a welfare argument for restricting it. Whether this can be done depends on whether **breed societies** and individual breeders feel it is important to do so. The welfare of domesticated animals would be promoted by avoidance of inbreeding, and matings should always be planned with this in mind. Modern computer techniques enable selection programmes to be designed that improve performance without increasing inbreeding excessively.

The relationship between inbreeding and behaviour is, essentially, that there are behavioural mechanisms in wild animals for restricting inbreeding.

Incentive motivation

Incentives are external stimuli that affect **motivation**. These incentives might, for example, be the smell of a certain food for a rat, or the sight of a hen for a newly hatched chick. The

P.341

value, or motivational strength, of a given incentive may be affected by learning.

(BAF)

Inclusive fitness

Inclusive fitness is a mechanism to calculate the spread or otherwise of a gene or genes through a population, that takes into account the effect that bearers of that **genotype** might have on different sorts of relatives. It is closely tied to the concept of **kin selection** and the evolution of **altruism**. The success

(or otherwise) of the gene spreading through the population is determined from Hamilton's rule: $rB - C > 0$, in which r is the coefficient of relatedness between the giver and receiver of aid, B is the benefit to the recipient due to the act of the altruist (often measured in terms of *additional* offspring gained due to the help given by the altruist) and C is the cost to the altruist (often measured in terms of offspring *lost* due to the diversion of resources from personal reproduction to assisting a relative).

In reality, the cost is often difficult to measure as it would require knowing how many offspring an individual gave up in order to help a relative raise more offspring. Thus inclusive fitness is a tool to help biologists compare the relative success of two or more behavioural strategies rather than an absolute measure of an individual's genetic contribution to the gene pool.

Individual differences

Individual differences are literally any variables that may be used to differentiate between individuals with some degree of reliability. Differences may be categorical (giving rise to distinct types of individual - typology) or continuous (giving rise to scores along a scale to differentiate individuals - the trait-based approach); thus height, sex, age, coat colour or behavioural or psychological factors may all be used as the basis for distinguishing between individuals. The issue of whether individual differences exist in relation to a given behavioural variable can be addressed by answering the question of whether certain types of individuals are more similar to themselves than others over time and contexts. This can be assessed by looking for significant differences in specific behaviours or by considering a range of responses using multivariate methods such as factor analysis, principal components analysis and cluster analysis. Certain types of consistent individual differences in behavioural tendency in animals are often referred to as constituting the animal's **personality** or **temperament**.

Although individual differences in behaviour may be qualitative (types) or quantitative (traits), personality is composed of a collection of differences in behavioural style, and so this is described most completely by using a trait-based approach. However, certain groupings within a trait, e.g the extremes, may be labelled as a particular type. For example, in response to a challenge, many animals are classified as being either 'active' or 'passive' copers, with the former tending to show escape behaviour and the latter tending to freeze. This classification represents their predominant behavioural style. It does not imply that a given individual will not show the other style on occasion, and it is also possible for many individuals to fall between these extremes; for example, the term 'active coper' could be defined as the upper ten rather than the top fifty percentiles of animals responding most actively to a restraint test.

Whereas most traits would be expected to have a normal distribution, this may not apply if there is a positive or negative bias in the advantage conferred by any aspect of the trait, or if artificial selection has occurred to shift the norm in a particular direction. For example, Sheppard and Mills (2002) found that sensitivity to punishment was reported to be negatively skewed, but sensitivity to reinforcement was positively biased in a population of pet dogs, which would be consistent with the selection associated with domestication (towards neophilia and away from **neophobia**).

Historically, individual differences have been seen by some as an inconvenience to experimental behaviour science since, if adequate measures are not taken to reduce them, there may be a high level of variance in a study, reducing the power to detect differences due to any treatment or other experimental variable, necessitating the use of larger sample sizes and increased resources as a result. For this reason, subjects may be matched or balanced within an experiment (matched pairs design) in order to control for certain variables and, while this is often done in relation to physical characteristics, it is less often done

for behavioural or psychological characteristics, although the use of certain strains or lines may help to reduce such variation.

There are several problems with balancing: first, it may not be known upon which parameters subjects need to be matched (or important factors may be accidentally overlooked, especially when the experimenter focuses on physical parameters); secondly, it may be difficult to find subjects that are closely matched. One way round this is to use subjects as their own control (within-subjects design, cross-over study or repeated-measures design), but this is not always feasible (especially if the study involves invasive sampling or the death of the animal to collect samples) and there may be an order effect (effect of exposure to the treatment on subsequent response to repeat exposure) or effect of the interaction between the treatments and order (cross-over effect) and, while these can be assessed statistically, if they arise, they greatly complicate the interpretation of the results.

Another alternative approach to the balancing of subjects between groups is to randomize subjects into the groups (randomized study), with partial (semi-randomized study) or no (fully randomized study) balancing between the groups and to use larger sample sizes to minimize the impact of uncontrolled variables. It might be argued that the fully randomized study is not in accordance with the **three Rs principle** that is adopted by many researchers interested in protecting animal welfare, although others may argue that it is the most scientifically pure type of study and so intellectually superior.

The importance of individual differences has been emphasized by several biological fields (including psychology). Individual differences are 'the raw material upon which natural selection acts' (Slater, 1981), and arise as a result of ecological variation in the distribution of essential resources. **Game theory** predicts that it will arise as a result of evolution, when no single trait (including any behaviour) is optimal in all circumstances. As such, individual differences may also reflect the variability and unpredictability of the environment inhabited

P.342

by a species that would prevent total adaptation. This is illustrated by the development of ever more elaborate and precise displays by many species living in relatively stable tropical environments, and the conservation of variation in animals living in more variable environments. Individual differences may also arise as a result of the advantages associated with **kin recognition** and the communication of individual identity (e.g. to prevent unnecessary **agonistic behaviour**).

The importance of individual differences in animal management, **conservation** and **welfare** is increasingly recognized as increased emphasis is focused on the importance of the individual's welfare and its value as a genetic resource. Different individuals may respond to a similar disease challenge or load from a **stressor** differently as a result of individual differences (personal risk factors), and so the physical and psychological **health** of an individual cannot be understood fully without an appreciation of the individual that is affected.

Recognition and appreciation of this is one of the essential skills of a good clinician. One of the challenges of medicine and the development of good husbandry practices is the identification of significant risk factors of clinical relevance relating to individual differences, i.e. those factors that are of real importance, and this will vary with the condition under consideration. For example, in the case of a potentially fatal problem, small risk factors relevant to small individual differences are important but, in the case of less serious conditions, such variation may be of less relevance.

To date, most work has focused on physical differences, e.g. skin colour and the risk of squamous cell carcinoma in cattle and cats, with less attention generally paid to behavioural and psychological differences, despite their potential importance in susceptibility to even infectious disease. The notable exception to this is the study of individual differences in behaviour as a risk of behavioural problems, e.g.

aggression and the risk of **cannibalism** in chickens, attachment behaviour and the risk of **separation anxiety** in dogs, etc.

An appreciation of the importance of individual differences in behaviour is therefore important to many aspects of applied animal behaviour and welfare.

Individual fitness

Evolution by natural selection is a potent force of adaptive change. Simply put, those individuals whose genes spread through the population have greater **fitness** than those whose genes do not. An individual's genes can spread directly and/or indirectly, and this distinction is important. **Charles Darwin** recognized possible ways that his hypothesis of natural selection could be challenged if individuals did things that directly benefited others at some cost to themselves. For instance, we often see animals helping feed or care for others, or emitting potentially costly alarm calls. How could these potentially costly behaviours be adaptive to individuals? The solution is that individuals share genes with relatives (they share more genes with close relatives and fewer with more distant relatives (**see: Kinship**) and, by helping relatives survive and reproduce, individuals are helping their own genes survive and reproduce.

The British geneticist J.B.S. Haldane once said that he'd be willing to sacrifice his life for two brothers or eight first cousins. Working through the maths, we see that saving two brothers will generate 1 fitness unit ($2 \text{ brothers} \times 0.5$, the coefficient of relationship between an individual and a full sibling), as will saving eight first cousins (8×0.125 , the coefficient of relationship between an individual and his first cousin). Thus, Haldane's back of the envelope calculation was correct.

There are a number of common confusions about the term fitness. Darwinian fitness is often mistakenly confused with physical condition. Evolution by natural selection does not inevitably select those in the best condition to reproduce; rather, those that reproduce have the highest Darwinian fitness. Envision an elephant seal. We typically think that large-bodied males are better able to defend harems and therefore

have higher reproductive success. In most years this is certainly so, and we see the largest males obtain the most copulations and sire the most young in a colony. However, what happens when insufficient food is available? We know that, in such conditions, females of some species may save energy by not breeding. Because large-bodied individuals require absolutely more energy than smaller-bodied ones, large males may be the most vulnerable individuals when food is drastically restricted. In this case, small-bodied individuals might survive and be alive to reproduce the following year. Thus, the largest animals, in apparently the best physical condition, might not have the highest fitness.

Elephant seals also illustrate another strategy. Large males exert a lot of energy defending their harems and fight viciously with other large males. Smaller male elephant seals look more like females. Because they have no chance of winning a fight with a large male, they do not try. Rather, on occasion, smaller males will try to mate with a female in a large male's harem. These males are referred to as 'sneakers', and this illustrates a condition-dependent strategy whereby large males fight for reproductive success and smaller males try to steal it. Such condition-dependent strategies are common and illustrate another way that 'being in the best physical condition' may not necessarily translate to having the highest fitness.

Fitness is a relative concept. Fitness will not lead to the best conceivable individuals or traits. Rather, heritable traits will evolve so that populations consist of individuals with those beneficial traits. When conditions change, what determines the best trait might change, and thus we will have selection for another trait. Moreover, traits do not evolve to some '**optimal**

P.343

fitness'; rather, traits evolve such that individuals with them do better than individuals without them.

Fitness is constrained in many ways. The fluctuating selection described above, whereby large animals might be favoured in years of plenty and smaller animals might be favoured in sparse years, will maintain heritable variation and prevent fixation of a particular trait. Additionally, if there are genetic correlations among traits, selection for a particular trait may be constrained by its correlated trait. Since we expect traits to be correlated, and since linkage is common, 'optimal fitness' will not be seen.

Individuals act in many other ways to maximize their individual fitness. Any time we see animals acting in ways that favour their personal survival, we see evidence of animals behaving in ways that suggest that individual fitness is important. Consider a fight between two male bull elk (a large deer). These opponents have a formidable set of weapons large, multi-pronged antlers. When two opponents meet they engage in a complex assessment ritual. They bugle, because the lowest frequency of an individual's **vocalization** is directly related to body size (larger animals produce lower-frequency vocalizations). This is an unbluffable display, and many potential competitors simply avoid larger opponents. They engage in parallel walks whereby opponents 'size each other up'; they lock antlers and push a bit. Only if very well matched will individuals initiate full-scale combat, because combat is risky. Animals could break a leg by falling, or be skewered with an antler. If an individual is small, and therefore likely to lose, it is much better to run away and come back and fight another day.

Fatal fighting is thus rare, and the conditions under which we see it are revealing. Fatal fighting is seen when the magnitude of direct benefit is large, and there is considerable skew in who obtains it (meaning that not all individuals will be able to obtain a needed resource) and when individuals have only a limited period of time to obtain it. In a mating context, we expect to see fatal fighting among animals with little residual reproductive value (i.e. among older ones that will die soon). We also expect to see more fatal fighting in species that have extremely short lives with a very circumscribed mating period.

(DTB)

Infanticide

Infanticide is 'a behaviour that makes a direct and significant contribution to the immediate death of an embryo or newly hatched (born) member of the performer's own species' (Mock, 1984). Infanticide by males and non-relatives occurs in many species, generally serving to increase the fitness of perpetrators (e.g. male lions have been reported to kill nursing cubs after a pride take-over in order to trigger females' return to receptivity). The phenomenon of mothers killing their own infants has been documented in diverse mammalian species including humans, **elephants**, silver foxes, **rodents** and domestic **dogs** and **cats**. Mothers of other species, including those commonly kept on farms, as companions, in laboratories or otherwise in association with humans, occasionally display violent behaviour towards their newborn.

Domestic ruminant mothers such as cows and ewes are rarely overtly violent, but neglect or abandonment will lead to the death of a minority of infants. Perhaps because it is so unpleasant, infanticide has frequently been described as an **abnormal** behaviour, but is probably more accurately characterized as a normal response to a particular set of circumstances. Sarah Blaffer Hrdy (1979) suggested that mothers might increase their **inclusive fitness** by killing their infants because of their low social status, in response to lack of resources, due to disturbance or because infants were abnormal or too numerous. All of these factors decrease the probability of offspring surviving to sexual maturity, and killing infants reduces the mother's investment where the probability of successful rearing is low.

The maternal repertoire of the domestic **pig** includes some of the most violent acts of any seen in commonly farmed species. The phenomenon was referred to in the 1920s as 'parturient psychoneurosis', and as 'hysteria' as recently as the 1980s. In pigs, 'savaging' starts during or soon after farrowing. The sow, which may or may not be generally restless, threatens and may attack piglets that are close by. The attacks can result in injury or death of one or more piglets, or occasionally of a whole litter. Savaging episodes can be very brief, consisting of a single or a few snaps, or continue for several hours in the absence of intervention. **Aggression** may spontaneously cease at any time, or may stop once piglets start to suckle. Savaging is not generally followed by **cannibalism** of dead piglets.

Reports of the frequency of savaging have varied widely: levels may change with time and it has been reported to be a 'contagious' behaviour, occurring in sporadic outbreaks. A large-scale Canadian survey of commercial hybrid pigs reported that 3.4% of gilts (first-parity sows) and 1.2% of multiparous sows killed one or more piglets. Counting dead piglets alone will certainly underestimate the magnitude of aggressive behaviour: studies involving videotaping of farrowing in farmed wild boar and domestic gilts observed that 30% displayed some aggression towards their newborn, although few attacks resulted in **injury** or fatality. In common with many species where **mis-mothering** is more common in young females, savaging occurs more frequently in sows having their first litters, and there is some evidence that sows which savage their first litters are more likely to be infanticidal with subsequent litters. Gilts that savage at their first parity may not be kept by farmers for a second farrowing.

Traditionally, pig farmers might treat the savaging sow with a diverse range of home remedies, which included giving her beer, perhaps due to the now discredited belief that the behaviour arose due to extreme thirst, smearing her face and the backs of the piglets with a kipper, smacking her with the body of a dead piglet or the application of a rubber boot top, secured with string, around her snout. Modern treatments include the administration of sedatives such as azaperone and/or temporarily removing the litter until the sow has calmed down.

Wild boar farrow in secluded nests under dense cover; hence, the degree to which they or free-living sows giving birth in semi-natural conditions are infanticidal (if at all) is unknown. While it is unlikely that savaging is a **captivity**-induced behaviour, intensive production might increase its occurrence. The effect of the farrowing environment is unclear - it has recently been reported both that the behaviour is more frequent in open pens than in **farrowing crates** and that there is a tendency for more savaging when gilts farrow in crates.

While the **stress** of confinement and thwarted nesting motivation in a farrowing crate may increase a farrowing sow's tendency to behave aggressively towards her piglets, it is easier for piglets to escape from attacks when their mother is restrained in a crate, so the consequences of piglet-directed aggression may be less severe. Regardless of whether farrowing crates are used, the farrowing environment in large, modern pig units can be noisy, busy and disturbing. Sows are unable to isolate themselves prior to giving birth, as they would choose to do if free living (**see also: Sow behaviour**), and these factors could contribute to savaging.

With few scientific studies addressing the causes of infanticide in pigs, savaging remains a poorly understood behaviour. Possible evolutionary correlates have been investigated, but there is little evidence to link piglet-directed aggression with factors such as dominance status or litter size. While other species (e.g. dogs, cats, mice) will preferentially kill small or sick young, this is probably not the case with pigs. Especially in farrowing crates, the first piglet that walks past an infanticidal sow's face is likely to be attacked - this may be an early-born or vigorous piglet. Savagers may be more nervous prenatally than non-savagers. Parturition postural behaviour has been reported to differ in sows that go on to savage. This suggests a role of **pain** or discomfort in triggering the behaviour, as does the reported link between savaging and prolonged parturition.

Modern pig production means that gilts (unlike their free-living counterparts) are unlikely to have encountered a piglet until they give birth. At the time of birth, they are often unable, due to restraint in a farrowing crate, to turn around and establish recognition through nose-to-nose contact. These factors suggest that a simple fear of novelty could contribute to some piglet-directed aggression, which is supported by a finding that 24-hours-a-day light around farrowing (which could have helped gilts to see and recognize piglets more easily) substantially reduced savaging deaths.

Inflammation

Inflammation in essence is an immunological response that is usually initiated as a result of trauma or infection. As an immunological response it encompasses a complex of specific reactions that together create the 'typical' symptomatic appearance of inflammation. These include reddening, heat, pain and swelling. In addition to these sensed or visible symptoms, inflammation also includes a cellular immune response involving the attraction of granulocytes to the site of the infection/trauma (**see: Immune**

system). Inflammation also causes increased vaso-permeability, allowing the immune cells to enter tissue. These granulocytes are responsible for the non-specific removal of invading microorganisms.

To illustrate the complexity of the inflammatory process, it is worth pointing out that the chemotactic **cytokine** released at the moment of trauma or infection is one of many cytokines that are responsible for the onset of the general signs such as the reddening, heat, pain and swelling. Inflammation can also occur as an overreaction against innocuous invaders of the host's own tissue, resulting in an allergic or autoimmune reaction. This is referred to as hypersensitivity, of which there are four distinct types: immediate (allergic, Type 1, e.g. anaphylactic shock); cytotoxic (Type 2, e.g. autoimmune haemolytic anaemia); immune complex related (Type 3, e.g. vaccine reactions); and delayed (cell-mediated, Type 4, e.g. response to tuberculin testing).

(FLR)

Inherited disease

An inherited disease is a disease that is primarily transmitted genetically. There may also be an environmental trigger or other component (epigenetic) making an animal predisposed to a specific disease, e.g. type of exercise when young and hip dysplasia in certain breeds of dog. An individual inherits half of its genes from its dam and the other half from its sire, and each gene is comprised of two alleles, one from each parent. If they both code for a disease then that animal will be homozygous for that disease. If the alleles are different and one allele is dominant to the other, the degree to which that animal may have that disease may vary (depending on the disease), or it may simply be an all-or-none effect, and so it may not have the disease at all. If the disease is influenced by more than one gene (i.e. it is polygenic, polymorphic), then the expression of that disease may vary according to various factors determined by the expression of other genes and the environment (penetrance). It is hoped that the sequencing of the genome of various species may help us to better understand such diseases and the factors that influence their expression.

Inherited disorder

It is suggested that virtually all animals carry some deleterious genes. Because of natural selection, deleterious genes tend to occur at a low frequency, and hence the incidence of any particular defect is usually so low as to not cause major concern. Additionally, in **free-range animals**, the chances of these deleterious recessive genes expressing themselves as disorders are reduced by juvenile dispersal strategies that reduce **inbreeding**. In contrast, the mating of relatives (inbreeding) increases the frequency of homozygotes, thus permitting the expression of disease. By creating artificial groups, the establishment of breeds increases the chances of individual mating with related **conspecifics**. Closed stud books are especially likely to compound this problem because they prevent the introduction of 'fresh' genes.

Inherited disorders are now recognized in all established breeds of dog and cat, but are also reported in horses, production species and a growing number of captive exotic species. Dogs provide the best example of the problem. As a species, they show unique morphological diversity between breeds and have been intensely bred within the closed stud book system since Victorian times.

Pedigree dog breeders compete to produce phenotypes that conform to a written standard that may include traits that compromise the quality of life. Many of the morphological and behavioural traits valued by early dog domesticators had direct utility and functionality, and were incorporated into the first breed standards when dogs left the working arena and entered the world of dog shows. Unfortunately, these days some breed standards place more importance on appearance than on functionality.

That said, many inherited disorders cannot be blamed on any breed standard; rather they emerge by chance as a result of the inbreeding that is an inherent risk of breeding within the current framework that pursues so-called purity (being related) rather than fitness for purpose. Strategies to identify harmful genes and avoid breeding from carriers are, at first glance, an adequate response, but they effectively reduce the number of individuals available for breeding within a breed and thus paradoxically can increase inbreeding. The prevalence of inherited disorders will continue to rise unless the rules of breeding are changed and traits compatible with quality of life are selected for as a priority.

Injury

An injury is any damage to body tissues that may be either invasive, and involve breaking the skin and exposing deeper layers of the body, or non-invasive, but cause deeper damage such as bruising (bleeding), or stunning, as with a **captive bolt**. Some diseases make body tissues more susceptible to injury, e.g. lupus erythematosus.

Innate

Innate refers to a characteristic that is largely affected by the **genotype** of the animal. Innate characters, including behaviours, result from the evolution of the species rather than from environmental factors or those acquired during an individual's lifetime. Innate behaviours are performed effectively the first time they are expressed. Examples of innate characters include eye colour, begging behaviour and yawning.

(KT)

Innate releasing mechanism (IRM)

An innate releasing mechanism (IRM) is a hypothetical, internal, neurally and/or hormonally controlled process that is responsible for releasing a fixed-action behaviour pattern (**FAP/FMP**) following sensory input from a specific stimulus (the **releasing factor**). The mechanism prevents the performance of the behaviour until the appropriate stimulus is perceived. For example, an IRM releases begging behaviour in herring gull chicks when the chick perceives, among other stimuli, the visual stimulus of the red dot on the parent's beak.

Insectivore

Strictly speaking, the term insectivore refers to a mammalian species whose diet is largely made up of insects, and which belonged as a result to the formerly recognized order insectivora. Birds and other species, including some plants, that have a similar diet may be referred to as having an insectivorous diet, but are not generally referred to as insectivores.

Insight and relational mechanisms

Relational mechanisms lie at the core of human cognitive organization, expressed in everyday language by terms such as 'bigger than' and 'smaller than' and in formal symbolic systems by logical arguments such as 'A > B'. Ordered as a series, e.g. A > B > C, such relationally based mechanisms support transitive inferences of the sort that, given A > B and B > C, A must be bigger than C - an important deductive form of reasoning believed to be the cornerstone of rational choice behaviour. Relations are also central to the human ability to classify objects and events using rules of group membership. Reflected in linguistic acts of reference such as 'that is a canary', our further ability to denote the canary as (also) a bird reflects hierarchical principles that crucially underwrite our ability to combine and recombine words into sentences and communicate propositions about the world.

Historically, it was held by many that such relational competences were unavailable to 'the brute mind', a view offered by the father of American psychology, William James, and reinforced by the work of his student Thorndike, whose classic studies of problem-solving behaviour with cats at Columbia University based on 'blind' trial-and-error mechanisms led to a characterization of non-human **intelligence**, retaining a powerful influence over many comparative psychologists to this day. Designed ostensibly to evaluate the extent to which cats locked in a box would immediately connect a successful response - such as pressing on the door panel - with escape and inducing in turn a sort of 'aha' response, Thorndike found instead that cats only gradually acquired the successful response, selecting it with progressive frequency from a range of competing responses within their repertoire. Thorndike concluded that the connection

between response and outcome was forged as the result of blind trial-and-error processes rather than the outcome of strategic

P.346

planning and a perception of the causal relationship between action and success.

For Kohler, on the other hand, such trial-and-error characterizations were the result of bad experimenter practice that disabled the subject from seeing the problem 'in the round', rather than a reflection of normative mechanisms. In the early part of the 20th century, Kohler presented apes with problems that were meaningful 'at first sight' and without having to make any overt response at all. For example, confronted with alluring bananas out of reach, they could recruit sticks to augment their reach or stack boxes to gain height and recover the prize. In contrast to Thorndike, Kohler found that apes would often make sudden solutions without requiring trial and error when they were in a position to perceive the putative relationships between the different components of a problem, instead of seeing the task piecemeal as in the case of Thorndike's cats.

This disparity between Thorndike's and Kohler's characterizations of animal intelligence provoked the philosopher Bertrand Russell to comment dryly that American rats learn by trial and error, while European rats learn by insight! For Kohler, however, 'insight' was a pale reflection of what humans might consider as thinking, regarding it as the result of a sudden (involuntary) perceptual reorganization. Since then, augmented by a new and burgeoning interest in comparative and evolutionary precursors to thought and **language**, a range of new paradigms has been evolved, often based on intensive learning procedures to parallel the life history and deep cultural immersion of humans. Critically too, some of these have been designed to eschew manipulation constraints that have long embargoed the deployment of free classification and other object-based tests so effective in charting human cognitive growth. As a consequence, contemporary comparative research reveals that non-human primates (at the very least) share some core conceptual representations, arguably the precursors of human propositional thought, reasoning transitively, classifying hierarchically and exhibiting flexible executive skills in serial ordering tasks. Of great significance for the issues of evolutionary origins and continuity, these ordering competences, moreover, also based on temporal relations, suggest significant evolutionary precursors for the highest forms of human achievements including language.

Some of these key building blocks of evolutionary cognitive growth, based on relational competence, are illustrated in the sections below.

Systematic relational competences

For Kohler, 'insight' in apes is driven by relationally based perceptual laws of organization derived (as he put it) from 'silent physiological operations' not accessible to conscious scrutiny. Yet humans, at least, are well aware of object relationships per se (and not merely the objects themselves). In language, for example, simple declaratives such as 'Jane is bigger than Henry' reflect an explicit grasp of the material (size) relationship in question. Humans also compute the inverse relation 'smaller than' from the declarative, as in 'Henry is smaller than Jane'. While contemporary evidence for relational learning by non-humans is strong, it is not systematic in this sense, one of the major problems being that the choice of relational tests used with animals has been somewhat *à la carte*, based on the isolation of a single relation such as 'brighter than', using choice methods that conventionally require the subject to choose an object either as 'brighter than' or 'darker than' its neighbour.

Figure 1.6 shows an important evolution of the conventional procedure. Here, the subject learns a 'language' of conditional signs where each sign signals which relational rule (within a set of five) must be chosen. Thus, if all objects varying in size are black, for example, the subject must select the larger/largest object (irrespective of its absolute size); if all white, by contrast, then the subject must choose the smaller/smallest object. As illustrated in Fig. 1.6, this method has revealed that squirrel

monkeys can acquire five related size rules, operating them systematically in ways very similar to that of 4-year-old children (McGonigle and Chalmers, 2002). In showing that rules are both systematic and available to non-verbal animals (at least primates), and that the type of relation itself can be linked with an arbitrary sign, we can conclude that core relational competences are reflected in language but not determined directly by language per se.

Relational competences and reasoning

Humans operate relations at a number of different 'levels'. First, they can detect these perceptually, as in the examples given above. However, a significant evolutionary advance centres on the human ability to reason symbolically as in situations where no direct perceptual information is present. Given several connected logical arguments, such as 'Jane is bigger than Henry' and 'Henry is bigger than John', human adults can order these items at a conceptual level and make the transitive inference that 'Jane is (therefore) bigger than John'. A key issue is the extent to which more abstract procedures of this sort are available to non-humans.

While the long-standing lack of positive evidence might suggest that they are not, one of the key difficulties here has been to present such tasks in a meaningful way to non-verbal subjects. With procedures that eschew language, we illustrate ways this can be done (see Fig. 1.7). In an adaptation of a reasoning paradigm designed for use with very young children (McGonigle and Chalmers, 1977), squirrel monkeys were trained on four connected pairs of tins of varying colour and weight; each pair was either heavy or light, but (crucially) the weight relation could not be perceived directly. The outcome showed that all six novel pairs (of the ten pairs that derive permutatively from the term series as illustrated in Fig. 1.7) were discriminated on the basis of a transitivity rule without further training. This was the first demonstration of 'reasoning' by non-humans under the most stringent conditions that developmental and experimental psychologists have been able to devise, now replicated extensively with a variety of species. However, significant variation in the procedures used since the first demonstration may support simpler solutions in certain cases.

'In the mind's eye'

Of course, no single source of evidence is definitive in this most difficult area. Instead, evidence is needed from tests assessing cognate cognitive competences. In linear transitive reasoning with human adult subjects, for example, subjects

P.347

often report the use of a mental image where test items are aligned along an imaginary spatial vector (usually a vertical one) with, e.g. Jane at the top, Henry in the middle and John at the bottom of it. Coinciding with subjects' reports of this imaginal process, it has also been found that decision times are often faster for transitive inference tests. That is, it takes longer to retrieve the pairwise information as given than to generate the inferences that derive from it, and this is known as the symbolic distance effect (SDE).

Squirrel monkeys (left) being trained on a series of five conditional rules of relation such that, e.g. 'if all blocks are red' then choose the smallest one, 'if all blocks are green', choose the second smallest, etc. until all five rules can be operated concurrently and in random order. The array changes randomly from trial to trial so that the rewarded item cannot be identified by a unique location. Performance on five-rule training as depicted followed training on smaller numbers of rules. Five-year-old children were given similar training and showed highly similar acquisition profiles to monkeys during the final single random alternation phase, as the graph illustrates (from McGonigle and Chalmers, 2002).

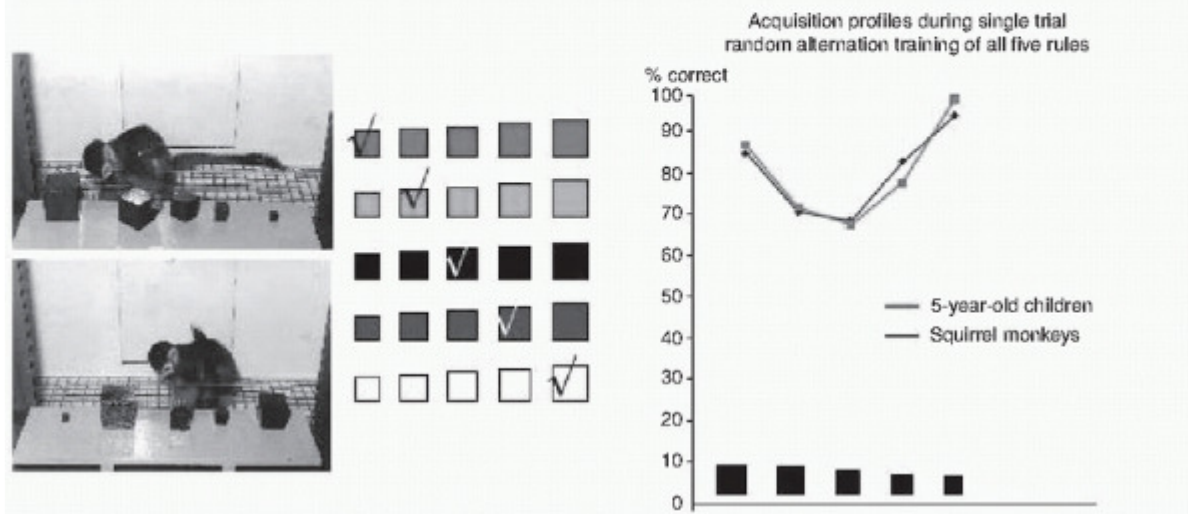

Fig. 1.6. Systematic relational learning: the acquisition of five size rules.

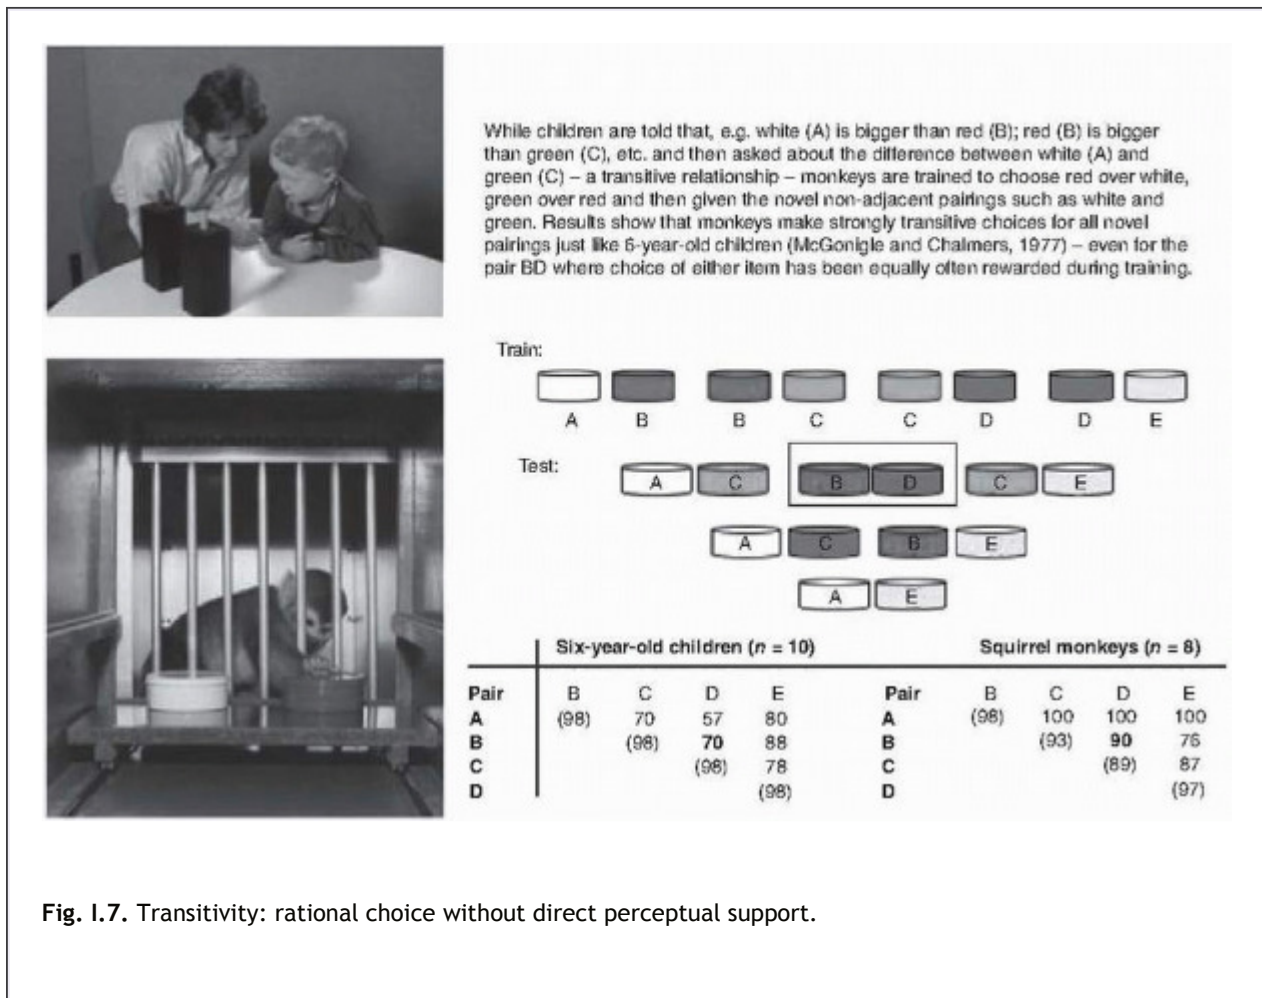

Fig. 1.7. Transitivity: rational choice without direct perceptual support.

P.348

Explained conventionally as being due to the fact that inference items are more remote on a spatial representation and less likely to be confused in a spatially based read-off, this phenomenon is also found in other tests of the mental representation of orders by humans when asked to compare a range of familiar objects conveyed as pictures or words 'in the mind's eye'. Once again, decision times are inversely related to ordinal distance and the mode of presentation is also important, with lexical representations of objects providing the slowest (absolute) decision times overall - although the psychophysical functions are similar. While we cannot hope to extract 'think aloud' data from non-verbal subjects, we can assess their decision time profiles obtained under similar conditions of test. As Fig. 1.8 shows, squirrel monkeys show a significant SDE for both perceptual and 'symbolic' modes of test, recording also, as with humans, slower decision times overall with the 'symbolic' mode - although the psychophysical functions are similar. This pattern of results based on decision time data points further in the direction of a 'symbolic' competence in non-humans.

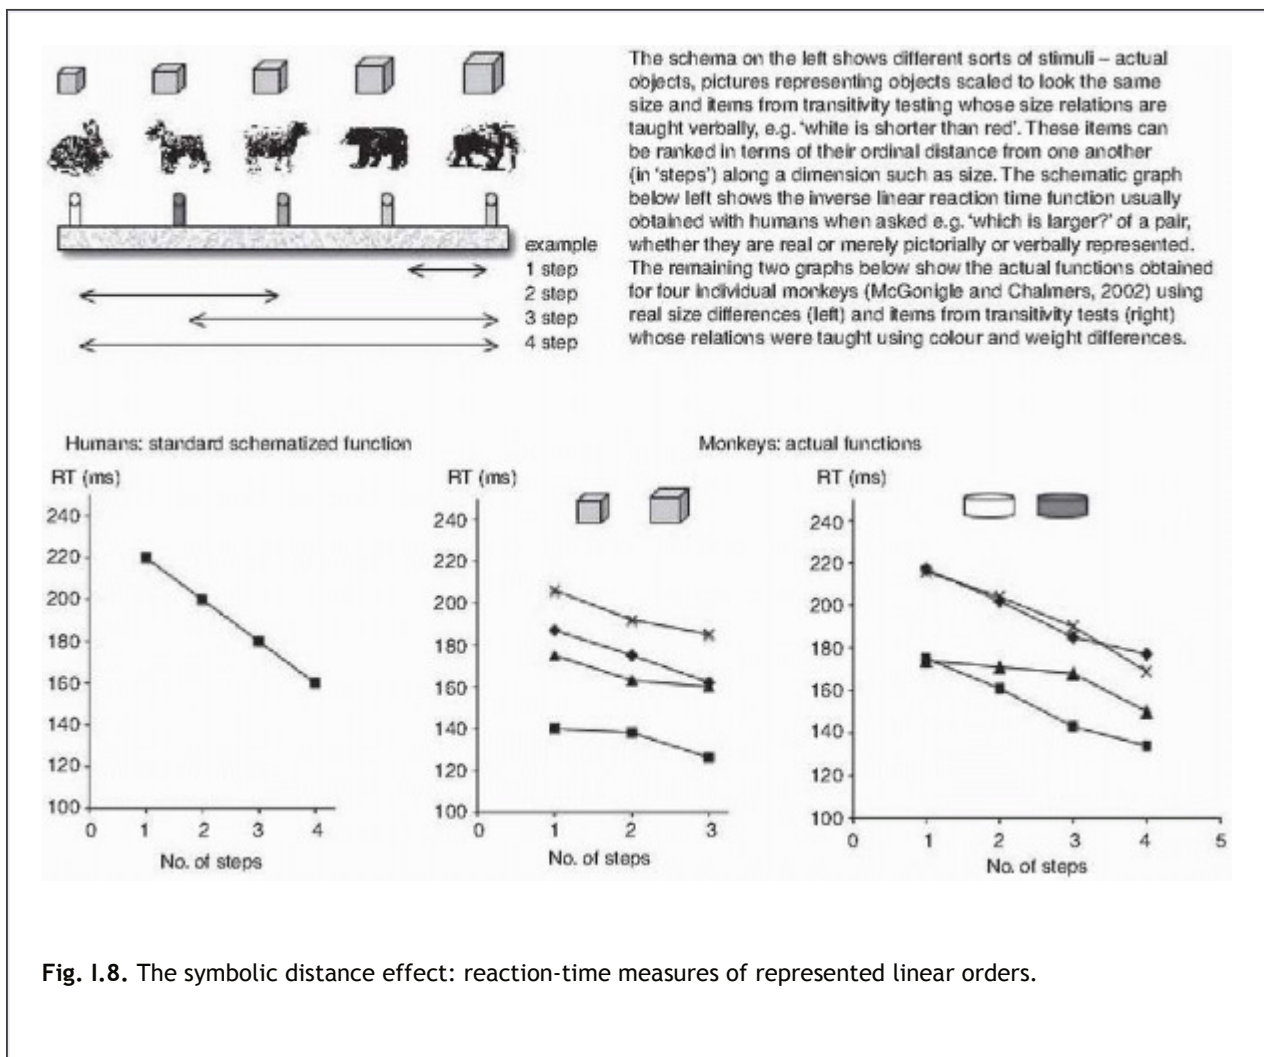

Fig. 1.8. The symbolic distance effect: reaction-time measures of represented linear orders.

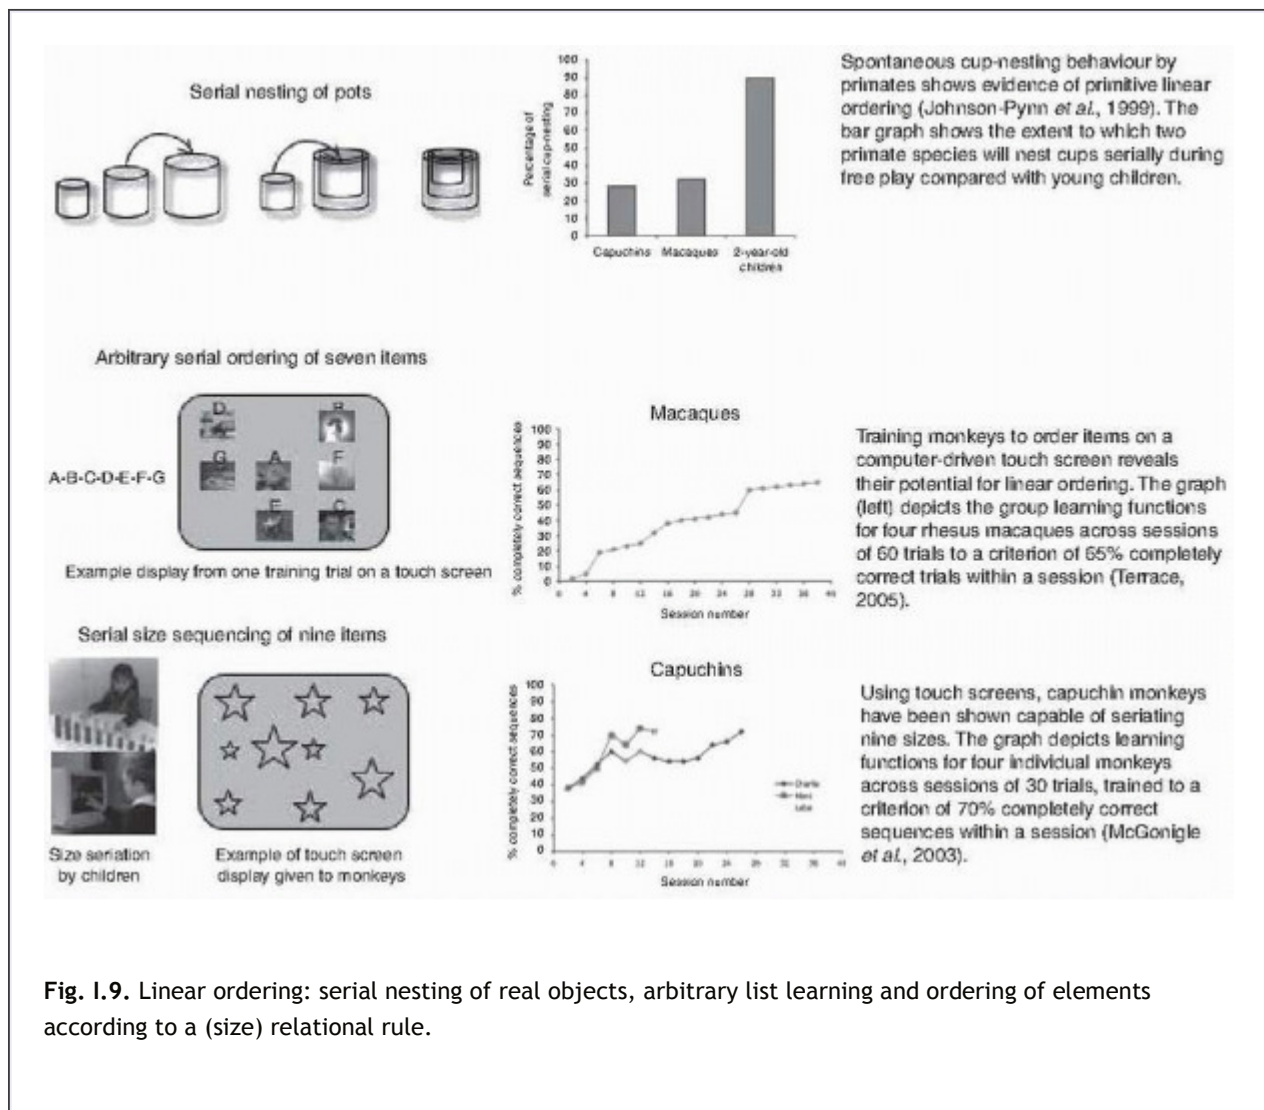

Serial ordering and executive control

Humans exhibit impressive feats of ordering as a core adaptive feature, controlling actions and words in extended productions that exhibit flexibility, capable of substantive recombinations. During human cognitive development, moreover, both the length of the child's utterance and the scope and extent of their ordering - as measured by the classic size seriation task - are a significant index of their cognitive growth. In the case of non-humans, by contrast, ordering mechanisms must be inferred from data conventionally based on binary choice paradigms, thus leaving a huge disparity between human and non-human behaviour in this domain.

Based on touch screens, new technology, however, has enabled investigators to assess the serial ordering competences of non-humans without requiring the high levels of manipulation required to place objects in a neat row, or to sort them into collections and classes. With touch screen procedures, the response requirements for each item are low-cost - a simple touch registered by the computer. Figure 1.9 illustrates this contrast, first showing sequences achieved by

P.349

primates required to nest cups in a manipulative test of principled seriation (Johnson-Pynn *et al.*, 1999).

As can be seen, the number of objects seriated is small. In contrast, touch-screen-based seriation is limited more by the size of the screen than by the primates' competence to seriate. This is illustrated both by the sequencing of a fixed arbitrary list by rhesus **macaques** where the elements have no material connection one to the other (Terrace, 2005), and also size-based seriation by capuchin monkeys (McGonigle *et al.*, 2003) using an iterative size rule (choose bigger). The monkeys' size seriation performance converges with that of 6-year-old children, both in terms of the length of the production and in its style (to count as successful, each production must be without error).

Categories and hierarchical organization

Humans deploy both linear and hierarchical structures in language and thought. The latter are revealed in the 'all/some' relationship and in the asymmetry between the use of the superordinate such as 'animal' and subordinate such as 'monkey'. Without such structures, **Darwin's** taxonomy would have been impossible. Based on a complex of equivalence and difference relations, the only option available to assess such high-level, adaptive competences in non-verbal subjects is to require them to sort objects into groups and collections (see Fig. 1.10). However, the high manipulatory demands entailed when using such conventional methods may be responsible for their meagre returns - a persistent result is that only one class can be identified from a group of objects, the rest left scattered and ungrouped. Given, however, that (even) non-human primates are relatively poor at object manipulation, conventional tests may have

underspecified their competences in this regard. Figure I.10 shows, by contrast, how sequencing on a touch screen can reveal substantial classificatory skills in monkeys, where capuchin monkeys (*Cebus apella*) classify nine test icons - presented in a randomized array on each trial - into three separate collections based on shape (McGonigle *et al.*, 2003).

In the first phase of tests, the exemplars within each category are identical; the monkey must interrogate all the exemplars from the category that must be sequenced first, then all the exemplars from the second category, then the final one, before the production is complete. In the second phase, the exemplars from each category vary in terms of their relative size. In this condition, the monkey has to order each exemplar as well as each category. As there are only three sizes of exemplar common to all categories, the monkey can only seriate accurately by coordinating the ordinal position of each exemplar with the ordinal position of the category from which

P.350

it is derived, and this requires a hierarchical form of control. These data show that monkeys can organize information hierarchically, now regarded as a vital precondition for the evolution of language itself.

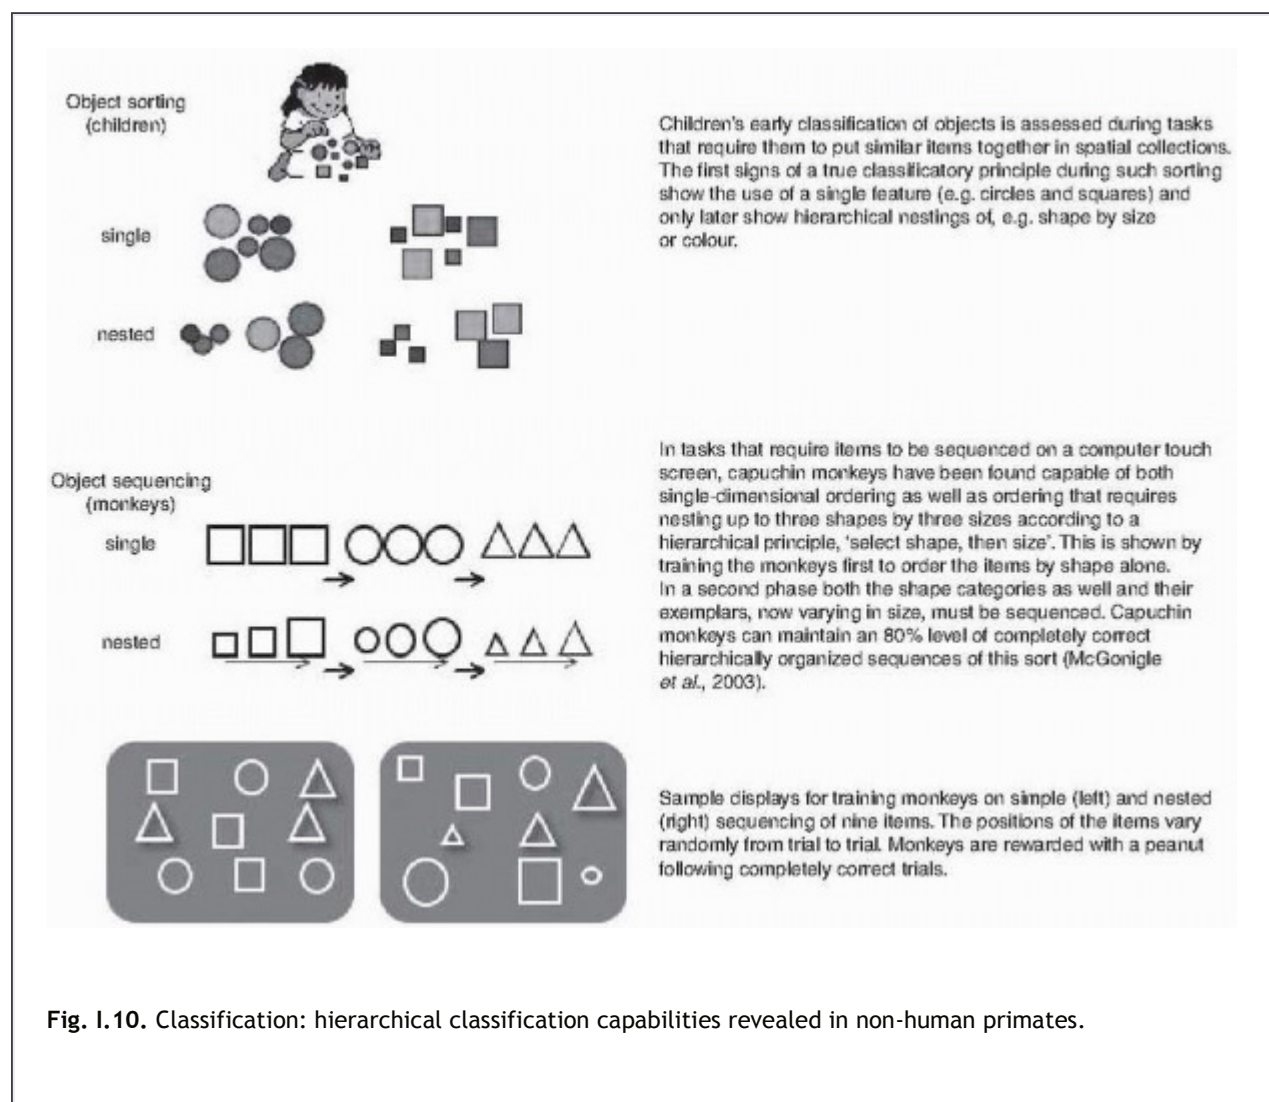

Fig. I.10. Classification: hierarchical classification capabilities revealed in non-human primates.

Conclusions

From the classic work of Kohler deriving from the early part of the 20th century, insight and relational competences have evolved as new paradigms and new technology empower the investigator to ask more focused question and eschew many of the linguistic and manipulative constraints on the expression of animal **cognition** that have traditionally left it underspecified. Now, insight and the ‘suddenness’ of a solution, as emphasized by Kohler, are less important than the unearthing of mechanisms for a principled solution that can underwrite planning and goal-directed behaviour in a non-reactive, intelligent way. Based on studies of ordering and executive functioning in particular, comparative research is beginning to reveal important evolutionary precursors to human cognition and language alike.

P.351

Instinctive behaviour

Traditionally, a behaviour was considered as instinctive when it was displayed in a fully functional form from its first appearance, and it showed a very limited degree of variation during the course of **ontogeny** and across individuals of the same species. This definition was based on the assumption that instinctive behaviour is under exclusive genetic control in contrast to learned behaviour, which may show greater variability among individuals and also in the same animal at different developmental stages. This view draws a clear dichotomy between instinctive-fixed and learned-plastic behaviour. Moreover, this dichotomy has led to the misleading view, which has attracted the attention of some scientists and of the popular public for decades, that instinctive behaviour is prevalent in ‘lower’ animals whereas learning characterizes ‘higher’ animals and humans. The current view rejects this dichotomy on the basis of two considerations. First, a clear distinction between learned and instinctive behaviours is basically

impossible, as every behaviour is, to some extent, under genetic control and even apparently fixed, while instinctive behaviour shows some degree of variability between and within individuals.

Imprinting is a classic example of a process that is traditionally considered instinctive, but in which learning is now known to play an important part. Imprinting is defined as a **sensitive phase**, usually in the early stages of an animal's life, during which attachment to a particular object/animal takes place. Imprinting is partially fixed, as during the sensitive period animals are genetically predisposed to react to an object or animal to which they are exposed; but it also is a type of learning, as imprinted animals learn to react to objects/animals and to improve their capacity to discriminate between them over the sensitive period. Secondly, the view that the importance of instinct versus learning is linearly related to **phylogeny** is over-simplistic and does not take into account the importance of the **ecological niche** of each species. Indeed, regardless, at least to some extent, of phylogenetic relations, species facing relatively fixed ecological conditions over their lifetime may efficiently 'rely' largely on instinctive behaviour whereas species living under highly variable ecological conditions have a stronger need to modify, through learning, their response to the environment.

Instrumental conditioning

The term instrumental conditioning (also called operant conditioning) refers to a form of associative learning/conditioning whereby the consequences of a behaviour influence its subsequent occurrence. For instrumental conditioning to occur, an action must be associated with a biologically relevant event (**reinforcement or punishment**) that changes either the probability of the behaviour recurring or some aspect of its form.

Insulin

Insulin regulates plasma glucose concentrations, production of alternative energy sources and the ability of glucose to enter cells of the body. The **brain**, an obligate glucose user, requires a constant supply of glucose. In periods where plasma glucose is reduced, i.e. fasting, an organism will maintain a steady supply of glucose to the brain by stimulating the production and release of glucose stored as glycogen in the liver, inducing non-neural tissues to use endogenous energy reserves (i.e. free fatty acids) and restricting entry of glucose into neural tissue only. In contrast, when glucose concentrations are high, these conditions are reversed. Insulin is the principal regulatory agent of these processes, where its presence allows for the systemic uptake and storage of glucose during periods of high plasma glucose concentrations.

Stored and released from pancreatic B-cells, insulin is composed of two straight peptide chains referred to as A and B chains, with 21 and 30 amino acids, respectively. The two chains are connected by two disulfide bridges; a third intrachain bridge connects two portions of the A chain. Insulin originates as a precursor, preproinsulin, composed of four consecutive peptides: the N-terminal, the B chain, a connecting or C-peptide and the A chain. During synthesis of preproinsulin, the N-peptide is cleaved, whereupon the remaining molecule is transported to the Golgi apparatus for final packaging. In this packaging process, the C-peptide is enzymatically cleaved and separated from the actual insulin molecule, though both are stored and released from granules in the pancreatic B-cells. The position of the pancreas on the hepatic vein 'upstream' from the liver allows that organ to quickly respond to alterations in plasma glucose concentrations as a result of pancreatic secretions. **Neuron(e)s** within the brain may

also possess the ability to produce and secrete insulin, although these results are weakly supported, particularly for the adult brain. The mechanisms described in this definition will not consider the brain's release of insulin.

The major releasing cue for insulin is increased plasma glucose concentrations, sensed by a negative feedback mechanism in the β -cells. Insulin release is controlled by an enzyme in β -cells - glucokinase - which serves as the first and rate-limiting step of insulin release. Glucokinase is active when plasma glucose concentrations are within an appropriate physiological range, initiating a G-protein system that causes granular fusion with the cell membrane and insulin release. The duration of this entire process is less than 60 s once heightened glucose is sensed. Conversely, a drop in plasma glucose concentrations will inactivate glucokinase, halting the G-protein system and subsequent insulin release.

Although plasma glucose concentration is the principal factor affecting insulin release, other factors can be potent as well. A variety of hormones (i.e. **cholecystokinin** and **glucagon-like peptide-1**) released by the gut in response to the ingestion of food enhance the glucose-dependent release of insulin. Products of digestion, such as amino acids, also enhance insulin release. Even the sight and smell of food preceding ingestion, referred to as the cephalic phase of digestion, induce insulin secretion, ensuring maximal uptake of glucose from the blood supply before being lost through excretion. Other factors inhibit insulin secretion, such as leptin, a hormone released from adipose tissue that decreases energy intake over both short- and long-term periods. Insulin will inhibit its own secretion as well.

Upon release into the bloodstream, insulin comes into contact with target cells in a number of tissues, principally the liver, adipose tissue and skeletal muscle. Once contact is made

P.352

with the target cell, insulin binds with the extracellular α portion of a glycoprotein embedded in the cell wall that has an intracellular β portion extending into the intracellular space. Binding of insulin to the extracellular portion initiates intracellular tyrosine kinase activity and allows for phosphorylation of insulin receptor substrates (IRS-1 and IRS-2). These substrates serve as docking sites and allow for the activation of other protein kinases, ion channels and cellular processes that results in the transcription or repression of genes that induce plasma glucose-regulating processes, i.e. activation of GLUT-4 that facilitates transport of glucose into the cell.

The specific processes that insulin induces are extremely broad and only briefly described here. During periods of high plasma glucose concentrations, insulin promotes the uptake and storage of plasma glucose into glycogen, thus reversing plasma glucose concentrations. These effects are seen in the liver and skeletal muscle. Principally in the liver, insulin also inhibits hepatic glycogenolysis, the breakdown of glucose from glycogen, and gluconeogenesis, the production of glucose from precursor amino acids. The liver will also store glucose in the form of free fatty acids in response to insulin.

Skeletal muscle, in addition to storing glucose, will oxidize a percentage for energy production and inhibit the uptake of free fatty acids, an alternative energy source, as a result of insulin binding. During periods of high plasma glucose, adipose tissue responds to insulin by promoting glucose transport into the adipose cell, where it is stored as triglycerides. Hormone-sensitive adipose tissue lipase, which causes the breakdown of triglycerides, is inhibited by insulin. Insulin promotes the transport of protein and amino acid into all tissues as well as inhibiting proteolysis, the breakdown of stored proteins.

The importance of insulin for normal functioning becomes apparent when this regulating system is dysfunctional, as is the case for type I and type II diabetes. Type I diabetes, or insulin-dependent diabetes mellitus, is caused by a genetic abnormality that eliminates or greatly reduces insulin production and secretion. Without insulin, glucose use by insulin-dependent tissues is greatly reduced and hepatic gluconeogenesis is continuous, resulting in extremely high levels of plasma glucose. Excessive plasma glucose will be excreted in the urine, pulling water and salts with it as a result of changes in osmotic potential, and induce **hunger**, causing the organisms to eat more, which worsens the situation.

Additionally, products of lipolysis and ketogenesis can cause a drop in blood pH and become fatal if prolonged. These and other symptoms are hallmarks of Type I diabetes. Type II diabetes, or non-insulin-dependent diabetes mellitus, has become a considerable problem in contemporary times as obesity and sedentary lifestyles have become commonplace. In this condition the body's cells become resistant to insulin, resulting in abnormally high plasma glucose concentrations.

Insulin-like growth factor (IGF)

Insulin-like growth factor (IGF) is a growth-hormone-like substance responsible for the development of a variety of tissues. In response to **stress**, growth hormone levels may rise, but IGF levels will generally fall. IGF is also of interest in relation to breed differentiations; for example, variations in the size of different breeds of dog have been traced to early variation (mutation) in the genes regulating the production of IGF.

Intelligence - comparative

An interesting aspect of human cognition is our seeming desire to classify others according to their level of intelligence (higher cognitive capacities). Ranking humans according to their intelligence has been divisive and controversial, mostly because measurement of intelligence is by no means straightforward. The most widely used psychometric test, the intelligence quotient (IQ) test, has been criticized because it is unable to measure intellect free from the influences of culture and previous education. It is also widely agreed that human intelligence is more than the sum of the parts that can be measured. Despite substantial criticisms, similar tests continue to be applied to human populations, e.g. cognitive ability tests are commonly given to 11-year-old UK school children, so that their subsequent academic progress can be related to this measure of their 'baseline' reasoning ability.

If assessing differences in human intelligence is so difficult, it might seem that comparing different animal species would be a hopeless task. And yet newspapers and websites are full of articles that ask such things as 'are dogs smarter than cats?'. Many scientists, too, seem quite happy to make certain judgements, e.g. 'animals differ in intelligence and humans are usually considered to be by far the most intelligent'.

Flowing from these assumptions, a large body of work has sought to understand what aspects of brain structure and function might underpin intelligence. Brain size is an obvious candidate but, as the brain size of elephants and whales exceeds that of humans, it is often dismissed. The most commonly cited correlate of intelligence is therefore *relative* brain size (i.e. the ratio of brain size to body mass). At first sight this seems appropriate; human brains comprise approximately 2% of body mass, a relatively high proportion for a large mammal. However, the relationship between relative brain size and intelligence is less clear when smaller mammals are considered. The brains of shrews, for example, comprise 10% of their body mass, but few would argue for shrews to be considered as being more intelligent than humans. These difficulties have not stopped the search. Other candidate features that have been examined as possible correlates of intelligence include: (i) the encephalization quotient (deviation of brain size of a species from expected brain sized for a standard species of the same taxon); (ii) the absolute or relative

size of the cerebral cortex; (iii) the size of the prefrontal cortex; (iv) the number of cortical neuron(s); or (v) the conduction velocity of the cortical fibres.

It could be convincingly argued that this whole approach is at best a 'fishing' exercise. Searching at increasingly greater resolution is almost guaranteed to uncover some neuroanatomical feature of the human brain that is larger, denser or faster than that of any other species. But this does not prove that the feature in question is responsible for human intelligence, or that we could in any way assume that animals with these larger or faster brain structures were more

P.353

intelligent than their smaller- or slower-brained cousins. Rather than making assumptions about the intelligence levels of different animals and then searching for neural correlates, others have argued that we should devise tests of intelligence that can be applied across different species.

Experimental attempts to compare the intelligence of different species have focused on differences in performance on cognitive tasks such as learning set formation. Such tests involve comparing an animal's later performance with its own initial performance, thereby measuring the extent to which the animal 'learns to learn'. The advantages of this approach are that many confounding factors, such as individual or species differences in motivation to achieve a food reward, can be eliminated. Early results suggested that rhesus monkeys became progressively faster at learning successive discriminations, showing a grasp of the general principles involved and applying these to new exemplars, whereas rats and squirrels showed little tendency to improve their learning speed over successive tasks. However, subsequent work shows that the exact nature of the cues used can significantly affect the ability to form a learning set. Dolphins and horses have both found it difficult to form a learning set when visual stimuli are used, but have been able to form one if auditory or spatial cues (respectively) are employed. If the specific nature of the cues provided can influence apparent intelligence within a species, then the difficulties of drawing conclusions about comparative intelligence between species should be very apparent. Species unarguably differ in their perceptual capacities and will adapt differentially to any testing environment. It may be that we can never fully overcome these confounding factors to provide a measure of pure intelligence.

There are two contrasting views about the nature of animal intelligence. The 'ecological' view of learning emphasizes the role of evolution in shaping cognitive mechanisms shaped for particular needs within specialised niches. This view predicts that there will be biological constraints on learning - for example, that animals will be able to associate novel tastes with subsequent poisoning but not novel sounds, or that chickens could be trained to work for a litter substrate by treading a panel but not by pecking a key - but it also raises doubts as to the existence of any unitary process of intelligence. Some adherents of this 'ecological' view believe that evolutionary pressures have forced solutions to specific problems that are dealt with by specialized psychological modules that may map on to particular brain regions or sub-structures. The logical outcome of this view is that all species are equally intelligent in their own ways.

The alternative, 'general process', view regards intelligence as a set of learning mechanisms, similar across all vertebrate species, that can be brought to bear flexibly to solve a range of problems. Proponents of this view argue that they have been unable to find any convincing examples of qualitative differences in cognitive processes between vertebrate species. They argue that associative formation is the critical problem-solving process available to animals and that the same mechanisms are relevant in all ecological niches. This view also regards all animals as equally intelligent - MacPhail's null hypothesis - although for different reasons. The truth may lie somewhere between the two claims, and it is perhaps most likely that cognitive function relies on general mechanisms complemented by a few specializations, such as the role of the hippocampus in spatial memory in food-storing birds, or the role of the Broca's area in human **language** capacity.

Scientists may not know whether dogs are smarter than cats, but at least they are starting to ask smarter questions.

Intensification of animal production

One of the greatest achievements of the 20th century was the dramatic increase in the efficiency of the production of food from plants and animals. Animal production scientists studying genetics, nutrition, animal management and animal disease have made possible a substantial increase in animal protein availability per person, despite a rapidly expanding human population. For example, **chicken** meat has changed since the late 1950s from a luxury, which few in any country could afford, to a widespread source of protein. However, some of the changes in animals and animal production methods that have made this revolution possible have had significant costs for the animals.

Genetic selection of animals in the course of animal breeding has changed the animals rapidly as knowledge of genetics has advanced. The rate of change is likely to be accelerated further if transgenesis and other genetic modification procedures are permitted (**see: Transgenics**). Selection has promoted fast growth, efficient conversion of feed into animal product and use of nutrients for growth and production of meat, milk, eggs, etc. In parallel with changes in the genetics of the animals, nutrient requirements and the means of supplying them have become much better understood. The magnitude of the effects is emphasized by the meat (broiler) chicken, which took 65 days to reach a weight of 2 kg in 1970 but only 35 days in 2000. Most of the rapid growth in animals kept for meat production, such as chickens, **turkeys**, **pigs** and beef **cattle**, is concentrated in the muscles and the gut, which is processing the food. Limb growth and the growth of the cardiovascular system are much slower; a consequence of which is a potential for leg and cardiovascular problems. Another is that, while meatproducing animals are fed *ad libitum* and grow very fast, breeding animals have to be starved in order to prevent obesity problems.

Other problems related to intensification of animal production are those associated with the reduction of space allowance in living conditions (**see: Confinement**) and

P.354

reduction in labour costs. Buildings cost money so, if more animals can be put in each building, costs can be lowered. In some systems, animals are housed individually so that feeding a known ration is easier and management does not necessitate having to deal with **aggression**. However, individual housing of social animals has been shown to cause poor **welfare** in all species that have been investigated. The use of small pens can cause lack of both exercise and much-needed resources. Minimizing space allowance can disrupt normal biological functioning. For example, pigs defecate in identifiable living areas but, if stocking densities are too high, they have insufficient space for differentiation of sleeping, lying and feeding areas. This is disturbing for pigs, and an animal that is normally relatively clean and careful not to injure group members may become dirty and perform injurious behaviours such as **tail biting**. In order to facilitate development in intensive systems, **mutilations** of animals such as **castration**, **tail docking**, **beak trimming** and **dehorning** may be used. These farm operations may be painful or prevent normal activities.

Dairy cows have been affected by intensification of farming, in that selection and feeding for high milk yield lead to increased levels of leg and foot disorders, **mastitis** and reproductive disorders, all of which involve poor welfare. High density of animals in housing conditions increases disease, while being kept tied for long periods also results in poor welfare. Calves kept for veal production are adversely affected by individual housing, lack of exercise, inadequate space for normal behaviour and lack of fibre and iron in the diet. Beef cattle have difficulties in coping with high stocking densities and may have leg disorders if growth is too fast.

Breeding sows were first put into stalls or tethered so that more could be kept in a building, individual feeding was easier and fighting could not occur. When the welfare of these animals has been compared with sows in well-managed group-housing systems, the welfare is clearly shown to be worse in stalls and tethers. The confined sows had high levels of **abnormal** behaviour, such as **stereotypies**, unresponsiveness and high levels of aggression, together with abnormal body and brain physiology. Farrowing sows have problems trying to cope with confinement in **farrowing crates** but, in indoor systems, piglet mortality is too high in various kinds of farrowing pens. Young pigs kept in solid or slatted-floored pens at a high stocking density, and with no material to root in or manipulate, show abnormal behaviour such as tail biting and excessive aggression. High density and lack of opportunity to show high-priority behaviour result in poor welfare.

The effects of intensification that result in the poorest welfare in chickens kept for meat production (broilers) are disorders of the legs, which result in difficulty in walking or inability to walk. Clinical diseases include tibial dyschondroplasia, femoral head necrosis, valgus-varus deformity, rickets and various forms of dermatitis resulting from birds with weak legs resting on alkaline litter. In addition to leg weakness, fastgrowing broiler chickens are susceptible to ascites. These common conditions, some of which also occur in turkeys and ducks, are a consequence of genetic selection, high stocking density and poor maintenance of litter quality.

Laying hen housing is quite different from that for meat chickens. Laying hens may suffer from broken bones because of lack of activity in cages, poor-quality handling and calcium metabolism problems associated with production of large numbers of eggs. If kept in battery cages, exercise is always insufficient and birds are usually not provided with a perch, a nesting place or litter or sand for manipulation and **dust bathing**. High stocking density and high metabolic demand cause problems that are also associated with the housing system used and how well it provides for birds' needs. In some countries, laying hens may also be forced to moult so as to enter a second laying cycle, usually by depriving the birds of feed for a 2-week period.

High stocking density also leads to problems in farmed fish. Trout and salmon can have insufficient oxygen in some circumstances when space allowance is low. They may also have insufficient access to food, may injure one another and are more susceptible to some diseases. Animals kept for fur production, which are

not domesticated in the same way as common farm animals, have poor welfare when kept in small, barren cages that do not fulfil their needs (see: **Fur farming**).

Intensification of animal production has led to poor welfare in many farmed animals, but welfare can be improved at relatively little cost if appropriate laws and codes of practice are enforced.

Inter-animal distance

This term was coined by Hediger (1941), describing it as the maximum species-specific distance at which conspecifics approach each other. Importantly, this description not only assumes that inter-animal distance is based on an animal's ability to represent distance, but also on its ability to represent itself in a distance matrix, and its ability to distinguish conspecifics from other entities. The exact distance at which an animal tolerates a conspecific or another animal is highly context-dependent, e.g. puppies tend to accept a smaller interanimal distance than older dogs, social species tend to accept a smaller inter-animal distance than solitary species, confined compared with open spaces enhance tolerance for smaller inter-animal distance and being sexually active or enjoying a lower ambient temperature enhances tolerance for smaller inter-animal distance (e.g. Bogusch, 2002).

In his later work, Hediger (1955) refers to 'critical distance' as the minimum distance at which an animal attacks and to 'flight distance' as the minimum distance at which an animal flees (see: **Flight zone**), while 'personal distance' refers to the maximum distance at which conspecifics feel comfortable, and 'social distance' refers to the maximum distance at which within-species groups feel comfortable. All of these notions are highly context-dependent, as described above. Since Hediger's (1955) publication in English, some of his notions have been incorporated into Anglo-Saxon-based anthropology and

P.355

psychology, and have been referred to as 'proxemics' (Hall, 1966) or personal space (e.g. Sommer, 1959). Recently, Graziano and Cook (2006) have speculated that the bodycentred receptive fields in the ventral intraparietal area and in the pre-central gyrus form the neural basis for the concepts of 'personal space' and 'flight zone' in macaques.

Interleukin

An interleukin is a form of **cytokine** that was originally identified as being produced by white blood cells and that has a wide range of stimulatory effects on other white blood cells. More than 30 different types of interleukins are now recognized, and many are not produced exclusively by white blood cells, although the term is still used.

International regulation of animal welfare

Since there is no global legislature, international regulation of animal welfare in a global economy is a potential cause for concern and tends to be done by convention, agreement to which by national governments is often voluntary. Following the publication of a convention, agreements may be developed dealing with specific issues arising from the principles laid out in the convention. For example, ASCOBANS is an agreement developed out of the Convention on the Conservation of Migratory Species of Wild Animals, which deals specifically with the conservation of small cetaceans in the Baltic, Northeast Atlantic, Irish and North Seas.

There are a number of conventions that impact on animal welfare and especially animal conservation, perhaps the best known of which is CITES (the Convention on International Trade in Endangered Species of Wild Fauna and Flora, or the Washington Convention), which aims to ensure that international trade does not threaten the survival of plants and animals (see also: **Endangered species**).

The Convention on the Conservation of Migratory Species of Wild Animals (also known as CMS, or the Bonn Convention 1979), mentioned above, is concerned with the conservation of certain migratory species over land, sea and air. The Bern Convention prohibits snares, certain devices and modes of trapping as well as poisoning to kill wild animals and, more recently, a Convention for the Protection of Animals Kept for

Farming Purposes has been published, and this is now enshrined in certain countries through their own national legislation, such as the Animal Welfare Act 2006 in the UK.

Different bodies are involved in convening the meetings that may lead to the publication of a convention, dependent on the special interest being discussed. Thus CITES developed from a meeting of the World Conservation Union (formerly IUCN), while the Convention on 'Good Laboratory Practice', which allows the recognition of **laboratory animal** test results internationally (and so reduces the number of **animal experiments** conducted globally), was produced by the Organisation for Economic Co-operation and Development (OECD).

Inter-observer reliability

Inter-observer reliability is the degree to which different observers give consistent results when observing the same phenomenon. There is the potential for an observer's past experience and sensory and perceptual abilities to bias what is attended to in the phenomenon being studied. Thus, a measure of the validity and objectivity of the data is the extent to which the observers agree about what happened.

(LMD)

Intersexual selection

Intersexual selection is one of two forms of sexual selection (**see also: Intrasexual selection**). The theory of sexual selection was developed by **Charles Darwin** (Darwin, 1871). He explained that competition for mates between individuals within a population results in differences in their reproductive success. The characteristics expressed by the most successful individuals are favoured by sexual selection as a result of their genetic material spreading through the population.

Intersexual selection occurs when an individual chooses one mate over another based on their particular morphological or behavioural characteristics. Preferences for mates can lead to the evolution of elaborate ornaments or secondary sexual traits - for example, the colourful tail of the peacock (*Pavo cristatus*). This is because competitors with the largest, most elaborate or conspicuous traits gain access to higher-quality or more numerous mates than unsuccessful ones, and so experience a higher reproductive rate.

Although secondary sexual traits can enhance reproductive success, they may also impose large costs. These may include impeding foraging ability, energetic costs or being more conspicuous to predators (**see: Predation**). The expression of secondary sexual characters will vary according to the cost of a trait balanced against potential reproductive benefits. The balance between the costs and benefits exerted by ornaments involved in intersexual competition frequently differs between the sexes, and can lead to sexual dimorphism (morphological differences between the sexes) within a species. In general, the

P.356

less particular of the two sexes tends to exhibit the greatest degree of ornamentation.

Males are frequently less particular and the more elaborate of the sexes due to the differing roles of males and females in **reproduction**. During reproduction females produce large gametes in comparison with those of males. Due to the asymmetry in gamete size, females tend to invest more than males per reproductive attempt. Females gain the most from being selective and lose the most from making mistakes, and so are typically the more particular sex. In many species males are polygamous. Male reproductive rate is constrained by the number of females that they can fertilize. Some may mate with many, others none, and so it is this sex that most frequently competes for mates. Males with traits that attract the most females will have the highest reproductive rates, resulting in a strong selective pressure for those traits. Monogamous species of males also compete for females, often for different reasons. Preferred males tend to be chosen first by females. Males that gain access to females before other males will gain a selective advantage, as those females tend to be in better condition and have higher fecundity. Breeding earlier in a breeding season is also an advantage, as resources are in greater abundance and a second brood can sometimes be fitted into one season.

For female preference to drive the evolution of exaggerated male ornaments there are two requirements. First, the preference should be directional. This usually means that the strength of a preference for an ornament is proportional to its size. Secondly, there needs to be sufficient variation between males in the size or quality of their ornaments for females to discriminate between them.

Several theories have been proposed that attempt to explain how mate preferences are maintained. Discriminating between potential mates may impose energetic costs on an individual or expose them to predators. Mate preferences will be selected against unless the benefits of being selective outweigh the costs. The two main theories, direct and indirect selection, consider how mate preferences may benefit individuals.

Direct selection refers to direct benefits such as increasing female fecundity and/or survival. For example, females gain direct reproductive benefits from choosing males with high-quality resources. If the quality of the male's resources correlates with his secondary sexual traits, females can identify which males have the best-quality resources. Territory size, parental care and sperm quality may all be advertised by male secondary sexual traits. For example, Howard (1978) found that male American bullfrogs (*Rana catesbeiana*) defend breeding sites of variable quality. Larger males obtain the better-quality sites and females prefer these larger males.

Indirect selection occurs when preferred males provide genetic material that produces offspring with high reproductive value. This may be offspring with enhanced mating success or survival. For example, many male secondary sexual traits are heritable and correlate with viability. Female preferences for male traits that indicate genetic quality are selected for as their offspring have a high survivability (good genes theory). For example, in the barn swallow (*Hirundo rustica*), female preference is correlated with male tail length (Möller, 1988). Males with longer tails sire offspring that experience fewer parasites in the nest and, as a result, have increased survivability (Möller, 1989, 1990). Parasite resistance is genetically passed down from these high-quality males to the offspring, so that mates of preferred males benefit from higher fecundity. Traits that advertise male quality act as a 'handicap' to the bearer such that low-quality males experience a greater cost to maintain them than they gain from the reproductive benefits (Zahavi's Handicap Principle). This ensures that advertising is honest. For example, barn swallow males with experimentally lengthened tails experience reduced foraging ability, and poor growth the following moult.

Heritable secondary sexual traits that do not correlate with viability may also be of indirect benefit to a female. The Fisherian runaway (or sexy sons) hypothesis predicts that once a preference for a trait has originated, a male trait and the female preference for that trait become genetically linked. Females with this preference gain from having male offspring that are attractive to other females, and this enhances

their overall reproductive success. The preference evolves as a correlated response to the evolution of the male trait. If female preference is directional and there is sufficient variation in the male trait, males with the trait become sexually selected such that the female preference and the male trait evolve in a selfreinforcing or 'runaway' fashion.

Debate on intersexual selection has, up until recently, focused on the evolutionary forces maintaining secondary sexual traits and the preferences for them. Current interest is now focusing on how traits and their preferences might have originated, and how intersexual selection may contribute to speciation.

Interspecific behaviour

Interspecific interactions can take a variety of forms. On a purely ecological level, one can look at so-called assemblage rules, i.e. how species' communities build up and which species promote or hinder coexistence. On the behavioural level, many interspecific interactions can be classified as competitive. One can distinguish competition due to similar diets, competition because the species are in a predator-prey relationship (see: **Predator avoidance**) and competition because the species are in a host-parasite relationship. Competition due to similar diets might often be difficult to observe, as species may have found 'evolutionary' ways to reduce behavioural competition. The smaller species might simply avoid the presence of the more dominant species and thereby avoid **aggression**.

P.357

Predator-prey and host-parasite interactions are different, as hosts and prey cannot solve the conflict by avoiding their enemies. These relationships are best described as an 'evolutionary arms race' that may lead to co-evolution: both sides try to stay ahead in their struggle and any successful **mutation** selects for a successful counter-mutation. Co-evolution in host-parasite interactions is much better documented than for predator-prey relationships. The problem with predator-prey systems might be that hunting techniques and escape strategies are often much specialized. Take the example of an antelope and a

pursuit hunter: faster-running predators may select for faster-running prey that selects for faster-running predators, etc., but to show that running speed has really co-evolved over time may seem like an impossible task.

A promising way to look for co-evolution between predator and prey is to look for systems in which: (i) hunting strategies and escape behaviour are quite flexible; and (ii) the outcome of the 'arms race' might depend on variation in ecological conditions. These assumptions are met in the 'arms race' between chimpanzees and their main prey, red colobus monkeys. A comparison between the Tai forest in the Ivory Coast and Gombe in Tanzania revealed that two parameters mainly influence the outcome of the 'arms race', namely relative size differences and the structure of the canopy. In Tai, size differentials between red colobus and chimpanzees are large (about 1:6) and the canopy is high and closed. As a consequence, red colobus males do not often defend their group members (they risk being killed as well) and all monkeys rely on **crypsis** at early stages of an encounter and escape routes during an actual attack. In response, chimpanzees actively search for their prey and then try to stalk their prey and hunt in a highly coordinated way to block prey escape routes. In response to stalking, red colobus associate with Diana monkeys that are particularly able to detect any sort of ground predators. Chimpanzees therefore avoid associated red colobus groups and mainly hunt in solitary groups. In Gombe, in contrast, red colobus males are large relative to the chimpanzees (about 1:3) and the canopy structure is broken. As a consequence, stalking by chimpanzees is not possible and the red colobus do not need another species as watchmen. As the monkeys cannot hide in the open canopy, chimpanzees do not have to search for their prey. Due to the limitation in horizontal escape routes, solitary attacks by chimpanzees can be successful and the main counter-defence is male red colobus aggression. Thus, co-evolution can be observed with respect to several components of predator and prey behaviour. A major unsolved question, then, is whether these adaptations and counter-adaptations are due to evolution on the genetic level or whether we are dealing with cultural evolution based on learning and tradition.

Mixed-species associations are a widespread phenomenon that occurs in a variety of primates and other mammals, birds and fish. Some of these associations may occur mainly due to chance encounters of individuals/groups with overlapping home ranges. In many cases, however, associations are actively formed and yield benefits to the partners. Benefits can either accrue due to increased foraging success or due to reduced **predation** risks. Often, benefits due to one primary advantage might create additional secondary advantages. For example, a reduced predation risk due to the association with another species may lead to reduced vigilance, which frees time that can be allocated to foraging. The relative importance of foraging and anti-predation benefits may vary according to the system under investigation. In the case of African forest monkeys, the anti-predation benefits appear to be the main selective force for mixed-species associations. In coral reef fish, however, commensalistic foraging associations are very common: several species that dig in the sand in search of prey are followed by a variety of species looking for flushed prey items. There is also apparent interspecific cooperative hunting occurring between groupers and moray eels in the Red Sea. On the other hand, many mixed-species shoals of fish have probably evolved to reduce predation pressure.

The frequent occurrence of mixed-species associations under natural conditions may be of animal welfare relevance, for example in zoos. Where space and intraspecific competition may often limit the number of individuals in a cage/enclosure, addition of allospecific individuals could augment the group without increasing conflicts. Group augmentation could reduce stress factors, such as being stared at by visitors, through dilution effects. An efficient way to use the occurrence of interspecific associations under natural conditions would be to merge adjacent cages/enclosures of species that tolerate/seek each other's presence. Under these conditions, individuals would have more space and larger group sizes while nothing has changed for the zoo in terms of animals per square metre. The only caution would be that species with different diets would probably fit together better under captive conditions than species with similar diets as, in the latter case, there is potential for strong competition between the species.

Also, visitors might find mixed groups more interesting to watch: mixed-species groups should be more active than monospecific groups due to perceived increased safety, and more social interactions will occur.

Intra-observer reliability

Intra-observer reliability indicates how stable an individual's responses are over different time points. A large difference in responses demonstrates low intra-observer reliability and a small difference demonstrates high intra-observer reliability.

(LMD)

Intrasexual selection

Intrasexual selection is one of two forms of **sexual selection** (see also: **Intersexual selection**). Intrasexual selection occurs in the form of competition between members of the same sex (usually males) for access to mates. Similarly to intersexual selection, intrasexual selection may lead to the evolution of conspicuous ornaments, known as secondary

P.358

sexual traits. These are involved in contests between members of the same sex and would otherwise be detrimental to survival according to natural selection. For example, display, song, coloration, size and weaponry may all be used during intrasexual competition. These ornaments may be totally absent in one sex, or present in a more elaborate form in one sex than the other, known as sexual dimorphism. Males are generally the more elaborate of the sexes in terms of secondary sexual traits, due to the different roles of males and females in **reproduction**.

While secondary sexual traits have no direct role in reproduction, they may increase reproductive success during competition. This competition may occur in the form of pushing, wrestling or other physical conflict. However, competitors often refrain from actual combat in order to avoid injury and, instead, engage in indirect assessment of strength or status via their secondary sexual traits. For example, male common toads (*Bufo bufo*) assess body size and thus the fighting capability of competitors through the pitch of their croak, so that males with deeper croaks are avoided (Davies and Halliday, 1978). The fighting ability of an individual can be also assessed through a series of ritualized displays.

In another example, red deer stags (*Cervus elaphus*) compete for females during each rut to obtain the largest harem, and therefore the greatest reproductive success. To avoid potentially fatal injuries, males

will withdraw from contests with males that they are unlikely to beat (Clutton-Brock and Albon, 1979). Male fighting ability is assessed first by the rate of roaring, as an indicator of physical condition. Stags that are well matched in their roars will walk parallel to each other, possibly to provide a closer assessment of their physical prowess. Only if the stags are still well matched will a battle commence, involving interlocking of antlers and pushing. As both winner and loser may be injured during these fights, it is of benefit to both competitors to settle a contest at an early stage, and escalation into actual fights is rare.

Secondary sexual traits used to assess other males are not always directly related to their combative strength. These types of secondary sexual traits may act as indirect advertisements of male fighting ability and are often termed 'status-signalling badges'. However, they may still act as honest indicators of male quality. For example, only the highest-quality males can maintain conspicuous secondary sexual traits while still avoiding predators. This indicates that a male bird with more colourful or brighter plumage would be more likely to win a contest than a more cryptic male. Badges of status are supported by dominant behaviour, and this also prevents cheating. For example, among male Harris sparrows (*Zonotrichia queula*), those with the darkest plumage are dominant over paler ones. Experimental darkening of plumage of subordinate males does not raise their status, as their behaviour does not alter (Rohwer and Rohwer, 1978). Dominant males are more aggressive towards other males, and it is this behaviour that backs up the visual signal of dark plumage.

Although intrasexual selection generally favours more dominant males, under certain conditions less dominant males can also experience high reproductive rates. In some situations these males may even experience greater success than dominant males. The differences in the costs and benefits of being a dominant versus a subordinate male may lead to alternative mating strategies. For example, in the coho salmon (*Oncorhynchus kisutch*), there are two genetic morphs of male with two distinct life history pathways (Gross, 1985). All the young fry start off their life in streams where they remain for 1 year, and then all migrate to the oceans. Females return to the streams to spawn when they reach maturity, at 3 years of age. Hooknose males also mature at 3 years, and also return to the spawning grounds. These males have conspicuous red coloration and enlarged jaws and teeth. A second type of male, the jacks, mature a year earlier and return to the streams after 2 years. They are relatively small and mimic females, as they lack any secondary sexual traits. On reaching the spawning grounds, females excavate nests where they deposit their eggs. Hooknoses fight between each other for access to the eggs of the spawning females, using their hooked jaws and teeth. The jacks avoid conflict and, instead, use their small size and inconspicuousness to sneak close to the spawning females. This enables the jacks to surreptitiously fertilize the eggs. As the jacks can get close to the females' nests, they have a good chance of fertilizing the eggs. However, the larger size of hooknoses means that they produce more sperm with each ejaculation.

Intrasexual selection can occur in even more subtle forms, such as via sperm competition. In some species females copulate with a large number of males and store their sperm in the body to be used for fertilization later. Male competition occurs by preventing other males' sperm from fertilizing the female's eggs. Some males have a modified penis, which can remove other males' sperm before depositing their own sperm. Other males deposit a sealant into the female's genital opening after copulating to prevent other males from fertilizing her; this is referred to as a copulatory plug.

The boundaries between intersexual and intrasexual selection are not always clear. For example, during sperm competition females may express a choice about which male's sperm is utilized for fertilization. Females may also 'eavesdrop' on male contests when making a choice about which male to mate with. Therefore, the evolution of a particular secondary sexual trait may be influenced by both inter- and intrasexual selection simultaneously.

Intraspecific behaviour

Intraspecific behaviour refers to all interactions that occur between members of the same species. Over their lifetimes, animals may engage in a wide variety of cooperative and competitive behaviours (both within and among the sexes) that are associated with **communication**, **territoriality**, **breeding**

P.359

behaviour and **group** living. In the wild, even animals that are primarily solitary during their adult lives almost always interact with siblings or other **conspecifics** when they are young, and with potential mates once they become sexually mature.

An appreciation of intraspecific behaviour is vital to: the establishment of successful **captive** rearing and **breeding programmes**; the maintenance of healthy zoo populations; the improvement of the welfare of domestic animals that are housed together; and the management of threatened populations in the wild. Accounting for behavioural interactions among conspecifics goes beyond separating aggressive individuals or bringing together potential mates; it must also including a firm grasp of the underlying **social** **behaviour** and breeding behaviour of the species one is trying to manage.

Signalling, communication and territoriality

Animals communicate with each other in a wide variety of ways. Visual, olfactory and auditory 'signals' evolve over many generations in response to the relationship between the producer of a signal, the recipient and the environment inhabited. For example, male tungara frogs (*Physalaemus pustulosus*) produce different frequency **vocalizations** that not only provide information on their location but also vary in relation to their body size. In several bird species found in noisy environments (such as near moving water), tail flicking and body bobbing have evolved as methods of communication, presumably because visual displays of territoriality are more efficient than vocalizations.

Animals can passively, as well as actively, defend their territories against encroachment by conspecifics. Passive territoriality includes methods of communicating without direct contact between individuals, such as through the use of scent. Giant pandas, for example, use scent glands located beneath their tails to advertise site-specific dominance. They may mark objects by squatting, backing up, cocking a leg or even performing a handstand to emphasize their stature. Many other species engage in scent-marking behaviours, not only through the use of scent glands but also through urine or faeces. In contrast, active territoriality often includes chasing or attacking intruders. In birds, however, active territoriality also

includes singing, which is used by males not only to attract mates but also to advertise their claim to a particular area so that conspecifics can identify the 'owner' of that area.

How and when animals defend territories is an important consideration in many applied contexts. Forcing normally territorial individuals to live too closely together might lead to aggressive displays, chronic **stress** or weight loss in less competitive individuals and, in extreme cases, **injury** or even **death**.

Conservation biologists and wildlife managers must also take territory and/or **home range** size into account when designing reserves, since reserves that are too small or fragmented may not be able to accommodate viable populations.

Breeding behaviour and alternative reproductive tactics

In order to maximize their reproductive success, individuals must be able to recognize and attract members of the opposite sex and select the best mates. Over evolutionary time, natural selection has led to the development and maintenance of an incredible diversity of mating and social systems. These include alternative strategies that exploit the energy of individuals other than the genetic parents, in order to assure offspring success.

Depending on the resources available, parents might pursue a number of alternative reproductive tactics. Female wood ducks (*Aix sponsa*), for example, can choose between establishing a nest in which they lay their eggs and incubate them, or laying them 'parasitically' in the nests of other females and providing no parental care. Younger, less experienced, females more often lay eggs parasitically; younger females frequently arrive later at the breeding area and thus have fewer nesting options than older females that have arrived earlier.

Males also pursue alternative reproductive tactics. For example, the dominant male in a group of savannah baboons (*Papio cynocephalus*) tends to follow the female around during oestrus, attempting to monopolize mating opportunities. However, subordinate males may work together in coalitions to competitively exclude the dominant male and gain access to the female. In species such as salmon, alternative tactics culminate in the presence of multiple male forms, or 'morphs', that compete for access to females. Salmon morphs consist of larger and competitively dominant 'hooknoses' and smaller, furtively mating 'jacks'. Males of the two morphs follow different developmental trajectories, are strikingly different in size and display completely different behaviours when attempting to mate (**see: Intrasexual selection**).

Group living

Many animals live in groups for part or all of their lifetimes. What are the advantages of living in a group, and what are some of the costs? Living in a group has many benefits, including increased **predation** vigilance, more effective avoidance of attacking predators (due to a dilution effect), reduced exposure to the elements and improved ability to find and defend certain food resources. There are costs to group living as well: (i) moving in a group may increase the chances of being detected by predators; (ii) disease can spread more quickly; and (iii) food sources can run out more rapidly. Thus, individuals should only live together when the benefits of group living consistently outweigh the costs.

In many cases, members of a social group are close kin (**see: Altruism**). This high degree of genetic relatedness may partially explain why some species breed cooperatively. Cooperative breeding is the social system in which adult individuals, in addition to the genetic parents, aid in the rearing of young. This system is rare in vertebrates but occurs in a few mammals (e.g. Latin American marmosets and tamarins, lions and African wild dogs) and in about 3% of bird species, including the white-throated magpie-jay of Central America. Among cooperatively breeding species, some individuals (frequently the offspring from previous years) act as babysitters, helping to feed and protect offspring that may not be their own. Individuals may opt to help rather than establish their own nests if territories are unavailable,

food is extremely limited or there are intrinsic benefits to remaining in the group (such as opportunities to learn parenting or foraging skills, or increased chances of breeding directly within the group). One fascinating example of a cooperative breeder is the naked mole-rat (*Heterocephalus glaber*), a furless South African rodent that spends its entire life in large underground

P.360

colonies. Similar to honeybees, each mole-rat colony has a single reproductive 'queen' and many non-reproductive workers that assist in colony maintenance and rearing of young.

Introspection

Introspection is the process of 'looking' into one's own mind in order to 'see' its content - e.g. what one thinks, feels or desires. Few psychologists or philosophers today would conceive of introspection on the model of sensory perception, however. Current orthodoxy is that there is no 'inner eye'. Rather, one discovers what one thinks and feels by wondering (or thinking about) what one would say.

(PAR)

Iron provision

Iron (Fe) is required for the formation of haemoglobin, the body's major oxygen carrier, and for oxidizing catalysts. It is also present in blood as ferritin and transferrin and in muscles as myoglobin. Milk has a particularly low concentration of iron in relation to other minerals, but in the suckling period there is often a store of iron at birth in the neonatal liver. The restriction of iron availability to bacteria limits their growth in the mammary gland and thus helps to prevent mastitis. Lactoferrin binds iron and thus controls its release in milk. It is particularly present in the milk residues in non-lactating mammary glands and in mastitic milk, suggesting that it has a protective role in limiting iron availability for bacterial growth.

Iron deficiency may be found in milk-fed calves and may be deliberately induced to produce pale meat, which consumers associate with tenderness. The deficiency is typified by anaemia, reduced appetite, poor growth rates and inability to cope with exercise. Iron also plays a part in the formation of

immunoglobulins, so that iron-deficiency anaemia is associated with reduced immunocompetence. Iron is very effectively recycled within the body and there is little urinary excretion. Iron absorption is enhanced in animals that are iron deficient, but the milk-fed calf will still develop anaemia within 8-12 weeks unless iron supplements are provided. Veal calf producers aim to create low muscle myoglobin contents without adversely affecting appetite or growth rate. This requires approximately 25-50 mg Fe/kg of dietary DM, although iron availability is variable. Milk contains only 5 mg Fe/l, and the stores provided to the calf at birth are therefore vital. Calves that suckle their dams at pasture invariably start consuming a few leaves of grass before the anaemia becomes established, and therefore are not at risk. The iron content of leaves is much greater than that of seeds or milk, and iron deficiency does not occur in cattle fed forage-based diets. Indeed, an iron supplement should not be added to the diet of adult cattle at risk of hypocupraemia, because it will inhibit the absorption of copper. Piglets reared indoors, in intensive systems away from natural sources of iron that they may encounter through foraging, may require additional iron supplementation to prevent anaemia.

Iron status can be assessed from the haemoglobin content of blood. There is a critical level at which the muscle myoglobin content will be reduced, but not growth rate or the animal's ability to exercise. Legally, in the European Union (EU), all calves must be fed sufficient iron to ensure that this minimum blood haemoglobin level (4.5 mmol/l) is met. If less than this, then a supplement of between 25 and 50 mg Fe/kg should be provided. Providing solid feed as required by EU legislation will also help to prevent low blood haemoglobin levels. There is a need for consumers to be more aware that red veal meat is of equally good quality as white meat and will indicate that the calves have not suffered impaired welfare as a result of hypoferraemia.

ISAE

The International Society for Applied Ethology (ISAE) was created in 1966 as the Society for Veterinary Ethology, with a primary membership of UK-based veterinarians. It quickly expanded to encompass clinicians and non-clinical researchers all over the world working in all areas of applied animal behaviour. It was renamed in 1991 to reflect this growth and it continues to be the principal learned society for workers in the field of applied **ethology**.

Islam

Islam shares the same biblical tradition as **Judaism** and **Christianity**, and thus builds on an ambivalent attitude towards non-human beings. The Islamic scriptures, the Koran and the Hadith, describe the ideal human-animal relationship. An animal-friendly perspective comes to the fore through several themes. One is the reward for those who are gentle towards animals: 'There is a meritorious reward for every act of charity and kindness to every living being' (Hadith Awn 7 222, 2533). A related theme is the reason for this - God loving all his creatures: 'All creatures are like a family of God; and He loves the most those who are the most beneficent to His family' (Hadith Mishkat 3, 1392). Thus, from this perspective of equality, 'A good deed done to an animal is as meritorious as a good deed done to a human being, while an act of cruelty to an animal is as bad as an act of cruelty to a human being' (Hadith Mishkat Bk 6, Ch. 7, 8, 178).

Even if the authenticity of these passages is disputed, i.e. whether they can be traced back to Mohammed or not, it shows that respect for animals was expected from a faithful Muslim in his time. From the 16th to

the 18th centuries, Europe was greatly influenced by Islamic thinking, including with regard to human-animal relationships. Complaining about European brutality towards animals, the philosopher Francis Bacon and authors like Alexander Pope and Richard Steele made references to Muslims, appreciating their care for animals.

P.361

Halal slaughter takes place in the name of Allah, during recitation of special verses of gratitude. As described in the Koran, calm treatment of the animal and a quick but smooth cut of the animal's throat is important. Blood is the sign of life and so traditional halal **slaughter** proceeds without stunning in order to bleed the animal. Freedom of religious expressions comes into conflict with many countries' legal framework for animal protection. However, negotiation on this issue has led some Muslim groups to accept stunning, for instance with electricity, which is the main method used in New Zealand and other countries.

Isolation

Isolation is a word used in varied contexts by people concerned with ethology and welfare. The term may be used, for example, in relation to issues of disease transfer, naturally occurring isolation of free-ranging groups of animals by geographical boundaries or the artificially occurring isolation imposed during animal management.

In relation to issues of disease transfer, the term 'isolation' can be applied to techniques used to generate animals free of particular disease-causing agents (such as the existing specific pathogen-free lines of rodents). In such cases, the stocks of animals are generally re-derived using an isolator to eliminate specified infective agents (such as viruses, bacteria and helminths) before being subsequently barrier-maintained to prevent reinfection. Elimination of disease agents is especially important in animals with immune deficiencies, such as nude mice, that are very vulnerable to infection. There is sound evidence that mild or 'latent' diseases can influence behaviour and physiology; these influences can alter the results of laboratory tests. In a related fashion, 'isolation' can be used as a synonym for quarantine, a technique used to reduce the chances of disease spreading to stock from newly introduced animals. New stock (in laboratories, on the farm, in zoos or in the country) is frequently held in relative isolation before being allowed to interact with existing residents. Individual laboratory, companion and zoo animals may also be isolated after surgery (to reduce the chances of **conspecifics** damaging sutures, etc. in anaesthetized subjects), sometimes with behavioural repercussions (see below).

Geographical isolation on 'islands' (areas cut off by geographical barriers - not always by the sea, as valleys and mountains may also restrict movement between locations - from the rest of the environment) provides opportunities for speciation (the derivation of new species from organisms colonizing first or already present). This is because these isolated locations provide niche opportunities, since these defined areas lack competition from specialist competitors, as found elsewhere. In addition, the pressures exerted by particular predators may be lacking. As a consequence, problems (the new species can become endangered or even rendered extinct) are frequently encountered when competitors or predators are

later introduced (either deliberately or accidentally). Human (anthropogenic) effects are increasingly common, especially with the ease of modern transport systems. Good examples are the endemic bird species found on Mauritius and the Hawaiian islands that have been subsequently endangered by the rat, cat, mongoose, goat and monkey species variously introduced by humans. The lemurs of Madagascar provide an example in which endangered primates are the focus.

In terms of management, isolation can take many forms. Isolation (as in the hatching of bird eggs in an incubator or the use of **hand rearing**) is one of the deprivation techniques used to establish whether a behaviour is largely genetically programmed. The assumption is made that, if the behaviour is expressed by animals that have not had the opportunity to copy the activities of peers or adult counterparts, it must have a strong genetic component. Isolation experiments may also be used to determine whether key experiences in so-called '**sensitive phases**' of development are essential for the genesis of specific behavioural elements, e.g. the 'dialect' component of bird song in the chaffinch (Thorpe, 1958) or aspects of vision in kittens. In both cases, the developing animal is restricted in terms of the communications it can receive from members of its own species. Such restrictions are generally limited to key stages of early development. The general strategy used in such experiments is to attempt to show that a particular experience has a less potent and/or not so lasting influence when the animal is exposed to it before and after the specified time, but the analysis of the results of such experiments is often quite complex due to potential interactions between time of treatment, duration of treatment, time of assessment and impact of assessment technique on the response obtained.

There has recently been renewed interest in the fact that isolating neonate rat and mouse pups restricts the development of their cerebral cortices (it decreases their size and weight), reduces the complexity of the neuronal connections (as studied histologically) and impairs the animal's learning capacity as expressed in a range of simple tests. Some of these effects can be ameliorated by the use of inclusions (toys) or '**gentling**' (handling). These studies generally confirm that social deprivation in early life has profound and lasting effects in a range of animals. The studies seem to be currently limited to mammals, but we know also, for example, that birds show '**imprinting**' in response to early influences. Hand rearing of birds may also result in the subjects fixating on inappropriate parents, siblings or mates. It is very difficult to reverse these effects. This means that such animals cannot be subsequently released in **reintroduction** programmes and have to be maintained in captivity. They may not only be unable to thrive following release, but can damage wild populations.

In his classical studies on mother-infant interactions, Harry Harlow showed that isolating baby female primates from their mothers resulted in their showing markedly impaired parenting skills (i.e. they were generally neglectful and inefficient mothers) when they became reproductively active in later life (e.g. Harlow and Suomi, 1971). This may also be of concern in **captive breeding programmes**, as it suggests that hand rearing (sometimes the only viable option for deserted or maltreated young) may well lead to the trans-generational passage of such deficits. A consequence is that the offspring of these animals will need to be 'helped' in this manner for generations.

P.362

The term isolation is most commonly used in the area of animal welfare, however, as a synonym for individual housing - for example, the housing of **laboratory** or **companion animals** in single cages, without direct physical contact with their conspecifics. One should note that such animals are rarely truly isolated as they generally have visual, auditory and/or olfactory contact with animals in neighbouring cages, tanks or enclosures. The same communication possibilities are certainly true of the housing conditions inherent in some intensive farming systems designed to reduce potentially damaging **aggression** by physically separating the subjects (**see: Intensification of animal production**).

Most early studies suggesting that isolation is stressful employed female mice, but this conclusion was based on the increased adrenal weights of such animals that do not accurately reflect '**stress**' (individual

housing increases **oestrogen** production in females and this hormone increases adrenal size in mice). Individually housed male mice generally show an increased propensity to fight. Valzelli (1973) claimed that the increased aggressiveness of such isolates was a consequence of the stress of 'social deprivation' (see: **Social stress**). From this viewpoint, the animals are considered to 'need' contact with their peers and, without such exposure, to show increased irritability. This increased irritability is then thought to reduce 'tolerance' and to increase the likelihood of the animal attacking a 'stranger'. This phenomenon was used to test anxiolytic drugs, as it was argued that a drug that reduced fighting must have ameliorated the social deprivation effect. Other workers have operated from the alternative viewpoint - that the isolated rodent is the animal least subjected to the social stress of crowding (in a standard cage it is at the lowest density). These viewpoints are actually diametrically opposite, with the former group assuming the captive animal needs social stimulation, whereas the latter maintains that they crave solitude.

Brain and Benton (1983) advanced a third alternative. They reviewed the available studies on a variety of behavioural and physiological attributes in isolates and group-housed male mice. Besides the well-documented augmentation of aggressiveness, individually housed mice show increased reactivity in a novel arena, higher motor activity in response to novelty, reduced turnover of a range of neurotransmitters, reduced adrenal weight, lower basal plasma **glucocorticoid** titre, heavier sex accessory glands, greater secretory activity of **pheromones** from the preputial gland, high gonadal **androgen** secretion, better coat condition, improved response to helminth **parasites** and better immunological responses to a range of (soluble and particulate) antigens than most group-housed counterparts.

It is self-evident that many of these changes are inter-linked. For example, androgens increase the size of the preputial gland as well as its production of sebum (a major pheromone in this species). Androgens improve coat condition by also increasing sebum production from the sebaceous glands associated with the hairs and may well increase body weight by their anabolic effects. Some workers have linked the elevated androgen levels in isolated male mice to their increased social aggression. In a similar fashion, the glucocorticoids from the adrenal cortex may be immunosuppressive and can change neurotransmitter levels in the brain.

As noted earlier, 'isolated' mice rarely completely lack social communication with their conspecifics. Investigations with mice have shown that negating olfactory communication reduces, whereas increasing these cues intensifies, the subsequent aggression characteristic of 'isolates'. Specific touch communication via the mystacial vibrissae (whiskers) seems only to have a minor effect on the later propensity to fight in mice. Other forms of **communication** have also been investigated. In the case of vision, opaque contact lenses have been used and do have a minor impact on behaviour. Congenitally blind mice are, however, perfectly capable of showing complex social behaviours such as fighting and mating. Anosmic (lacking the sense of smell) male mice, however, will neither fight nor mate. The impact of audible (to the human ear) sound and ultrasound (frequencies higher in pitch than those we can detect) do not appear to have been investigated, which is surprising as sound is used in conflict in a range of rodent and other species. Another study that attempted to totally isolate male laboratory mice from sensory communication with all conspecifics (in special ventilated boxes with activated charcoal filters) found that this procedure actually markedly reduced aggressiveness in these animals. These subjects appeared hyperreactive but largely fearful when paired with docile opponents. The studies in combination suggest that some forms of sensory communication (especially odour in mice, as vision is not very important in these basically nocturnal animals) actually modulate the effects of isolation on aggression, but that the main factor responsible for the associated behavioural change is lack of direct physical contact.

Strong parallels between isolates and socially dominant male mice were obtained using the same behavioural and physiological measures employed in the isolated versus group-housed mouse comparisons.

There is evidence, using genetic markers in mice, that only the socially dominant animals are reproductively active. The changes in isolated mice might also prepare them for breeding. The fact that many of the behavioural and physiological changes in the isolated mouse seem beneficial and that they parallel changes in the social dominant make it appear unlikely that one can simply dismiss isolation-induced aggressiveness as a consequence of social deprivation. Indeed, they suggest that the changes reflect a propensity to assume a form of **territoriality** in males of this species. If this is the case, and mice are not always a social species, group housing may not always be appropriate in these animals even if the intention of such housing is environmental **enrichment**.

A review of the literature comparing isolated and group-housed laboratory rats has been undertaken. It was initially anticipated that rats (because wild rats are generally colonial rather than individually territorial) might respond very differently to such housing than mice. It was noted that the comparisons were, however, often confounded by the imposition of stress on the animals during, for example, blood sampling. Studies in the rats also showed that a very wide range of hormones were changed by very minor disturbances such as opening the laboratory door or switching on the lights. There was also some evidence that the normal mechanisms of behavioural inhibition were impaired in isolated rats. They appeared slow to abandon previously learned behavioural strategies when the conditions were changed (so that the outcome was no longer rewarding) and were generally slow to habituate (**see: Habituation**). This suggests that rats become less behaviourally flexible as a result of the isolation. Somewhat

P.363

surprisingly, in general, the results with rats were often similar to those with mice (social organization did not actually appear to have much of an effect). It was concluded, however, that isolation versus group housing comparisons actually look at differential housing rather than 'social deprivation' or crowding. The choice of the baseline in such comparisons is really arbitrary. Having only two conditions also makes interpretation of the results difficult.

As one might expect, the age at which male rats and mice are differentially housed alters the amount of aggressive behaviour that they show following individual housing. The highest level of aggressive behaviour following a fixed period of individual housing in mice was seen in intermediately aged animals. Isolating mature group-housed subjects, however, may result in relatively high levels of aggressive behaviour in some lines of mice. Conversely, male mice cohabiting with other males generally show low incidences and intensities of fighting. This may be a consequence of their habituating to the odours of other mice (there may be a colony smell), developing a learned inhibition by the establishment of a social hierarchy or gonadal hormone secretion in subordinates being suppressed (this would reduce the production of the pheromones that normally stimulate attack in males of this species). It is likely that only despotic dominants from each group rapidly evidence marked fighting behaviour. It may take longer periods of isolation to produce similar changes in subordinate animals.

Mature, outbred, albino mice of the Swiss line show a very rapid (within 24 h) increase in aggressiveness following isolation. This ability is retained over a substantial period of adult life, suggesting that this line shows a strong tendency to assume a territorial habit. Age (rather than time in isolation) seems the key to determining the response to individual housing of Swiss mice. It must, however, be noted that mice from different genetic lines show very varied responses to individual housing. In some lines of mice, pairing a male with a female for breeding activity also augments his aggressiveness when he subsequently encounters other males. Reproductive activity also augments testicular androgen production, and breeding males lack direct physical contact with other males for the duration of the breeding attempt (they are effectively 'isolated' from them). It can be impossible subsequently to socially house such animals, which can create husbandry problems (individual caging takes up a great deal of space and other resources).

Having said that, the responses of laboratory rats and mice to isolation are remarkably similar in spite of their very different social organizations, and one should not get the false impression that all animals show

identical behavioural and physiological responses to such housing. In golden hamsters, the female rather than the male is the more aggressive sex and her behaviour is largely influenced by **progesterone** (rather than androgen). Androgens increase the size of the adrenal cortex in the golden hamster. The details of responding to isolation in this species are likely to be different from more 'traditional' rodents.

There is an urgent need to fully understand the effects of isolation on animals as imposed at different times in their lives. For example, isolating animals in adulthood generally makes it difficult to subsequently group house them. If the studies on rats and mice are representative, the particular aspects of behaviour and physiology changed are likely to be wide ranging and complex. Studies on a much wider range of species and contexts are needed for laboratory, farm, zoo and companion animals.

Istwert

The term istwert is used in applied animal behaviour to refer to the perceived reality of an animal at a given time. In this context it is recognized that animals respond to the world as they perceive it, rather than necessarily to the physical reality. The concept embraces the notion that different species (and different individuals) live in different perceptual worlds (umwelts) and it is this that influences their behaviour and welfare. Thus, an approaching individual may be perceived as a potential threat by some, but a source of social support by others. The physical reality at the time is the same for the two groups, but they have markedly different experiences and impacts on welfare.

Jainism

Jainism has its origins in India, and was founded in the 6th century BC by Mahavira. *Ahimsa*, non-violence, is its central principle. 'With the three means of punishment, word, thoughts, and deeds, you shall not injure any living being' - Jaina Sutra (Preece, 2001). It is applied not only through vegetarianism, for Jains also actively work for animal welfare, for instance by running animal hospitals.

Japanese quail

Japanese quail (*Coturnix japonica*) are small terrestrial birds of the pheasant family, which are farmed for food and used in **animal experiments**. Important quail behaviours include **foraging**, **dust bathing** and social interactions, so welfare is poor in barren cages. Good housing should provide cover, e.g. shrubs, and nesting boxes for laying hens. Thoughtful husbandry and early **habituation** to humans are essential, since rapid, upward escape flights can cause head injuries.

(PH)

Journey times

Generally, longer journeys will be more stressful to animals than shorter ones under the same conditions. **Transport** time can therefore be a significant factor influencing animal welfare. This is particularly likely

for animals transported under more austere conditions, such as those sent to **slaughter**, where there are commercial constraints on space allowances and levels of comfort. The method of transport is often related to journey times. Transport by air is relatively rapid, but that by road - and especially that by sea - is likely to be longer. Air travel is usually restricted to especially valuable animals, for example **pets**, breeding stock, racehorses and exotic and zoo **animals**. Individual journeys for slaughter animals are often part of a more complex process in which they pass through live auction markets. In this case the total travelling time, when all stages of the overall journey are added together, may be very prolonged.

Journeys within national boundaries

In North America calves and piglets are widely transported from breeding to fattening units, the process taking up to 24 h. In Australia animals can spend several days travelling to slaughter. Even in a small country such as the UK, journey times from farm to slaughter of up to 16 h have been recorded, although average times are much shorter (2-5 h). Published average figures from surveys carried out in the UK are 2.7 h for broiler chickens, 2.2-4.5 h for turkeys, 2.3 h for pigs and 4.7 h for sheep. Because of the trend for animals to be killed in fewer, larger slaughter plants, these times may tend to increase in the future. There is a particular problem with spent hens (birds culled after their economically worthwhile egg-laying life) in the UK, which may experience very long journeys simply because of the very small number of poultry processing plants that will accept them. Against this tendency is the realization by some more enlightened sectors of the slaughter industry that long transport is potentially detrimental to both animal welfare and the quality of the final product, this therefore leading towards pressure for shorter journeys and better-integrated delivery systems.

Extremely large numbers of broiler and layer chicks and turkey poults are transported from hatcheries to growing units worldwide. For example, worldwide in 2002 about 40 billion broiler chicks were sent to rearing units. Because they are newly hatched, and still reliant on their yolk sac for sustenance, the journey times are necessarily limited; however some chicks undoubtedly travel for up to 24 h. European legislation prohibits longer times without the provision of food and water.

Journeys across national boundaries

Exported meat animals can travel very long distances. Within Europe about 10% of commercial animal transport consists of journeys longer than 8 h. Large numbers of sheep have been transported from the UK to Spain, Italy and other countries in southern Europe, journeys taking several days, cattle are exported from Ireland to southern Europe and pigs are exported from The Netherlands to Spain and Italy - journeys of up to 1500 km sometimes lasting up to 40 h. The EU imports more than 2 million animals a year and exports about 300,000 cattle to North Africa; calves are sent from Poland to Italy and horses from central and eastern European countries, especially Poland, are imported into southern Italy, journeys taking perhaps up to 90 h. Outside Europe, Australia is one of the largest live animal exporters, sending large numbers of sheep by sea to the Middle East. This trade can often be of particular concern from the point of view of animal welfare, because of the length of the journey and the potentially poor conditions at sea.

P.366

In the USA, transport of livestock by rail or on board ships is limited to a maximum of 28 h without feed and water. However, this rule does not appear to apply to road transport. Long journeys in Europe must by law be interrupted at intervals by rest periods at designated staging points. However, a concern is that there is sometimes poor enforcement of these requirements, as there is of maximum permitted journey times, by the relevant national government authorities. Many animals, particularly those that have a relatively low individual economic value, such as animals exported for eventual slaughter for meat, may therefore travel longer than is allowed. Controlling this trade is made all the more difficult because it

crosses national boundaries. An integrated and strict enforcement of legislation would undoubtedly improve the welfare of a significant number of animals.

The welfare implications of long journeys

Transported animals are often confined in an unfamiliar environment and subjected to noise and sometimes vibration. They may be mixed with unfamiliar animals and exposed to environmental temperatures and humidity outside their normal experience. They may suffer long periods of food and water deprivation. It is likely that many animals will experience **fear** and **distress** and become fatigued by the physical exertion associated with the journey. Some may become bruised or otherwise injured through falling. The longer the journey the greater will be the effects. In extreme cases individuals will die. Where large numbers of animals are transported confined under often poor conditions, mortality rates are often high. For example, the mortality of broiler chickens transported to slaughter averages about 0.2-0.3% and can, under particularly adverse conditions, rise to above 10%. Even at the average figure, because the total numbers transported are so high, the overall numbers of birds dying are considerable. Based on the number of broilers slaughtered worldwide, if the average transport mortality were 0.2%, this would equate to at least 80 million birds every year. Mortality rates in exported exotic birds and reptiles are often very high because of the difficulty of maintaining suitably stable conditions of temperature in journeys that may last days, even by air.

Moving animals provides a mechanism for the spread of disease, both between individuals transported together and geographically. The latter is especially a problem with animals unloaded and rested at staging points, where the potential for cross-infection is high. The **stress** associated with transport may also make animals more susceptible to infection by suppressing their immune responses. Disease has obvious welfare implications as well as the economic costs. An example is the outbreak of foot-and-mouth disease in the UK in 2001, the initial rapid spread of which was at least partly attributable to the extensive movement of animals throughout the country.

(PDW)

Judaism

Within Jewish scriptural tradition the relationship between Yahweh and his beloved Creation is thoroughly considered. The Torah principle 'do not destroy' has explicit reference to treating animals well in Talmud. In order to be kosher, slaughter has to be performed without **stunning**, with a sharp, long knife, accompanied by prayer and calmness. However, in industrial kosher slaughter, animal welfare is much compromised.

Juvenile behaviour

It is common in long-lived species for individuals to have a prolonged period of immaturity prior to reaching adulthood. Early in their lives, young birds and mammals are dependent on one or both parents for nourishment, but even after the point at which they are fledged or weaned there is often an extended period of close association with their parents. During this time, the behaviours they commonly exhibit may differ markedly from those seen in adults.

There have emerged two schools of thought regarding juvenile behaviour. On one hand, behavioural development can be thought of as a process by which young animals add behavioural components to their repertoire in a building-block fashion, continually refining those behaviours until they reach adult form. Under this view, a juvenile is incapable of expressing fully competent 'adult behaviour', and repetition of the juvenile (incompetent) form of the behaviour allows the juvenile to acquire the competency necessary in adulthood. A second perspective has more recently emerged, which views the behaviour of immature individuals as being adapted (as a result of natural selection) for a particular life stage. Natural selection operates at all stages of the life cycle, thus the behaviour of juveniles may differ from that of adults because they experience different social and physical environments than adults. Within this context, the distinctive behaviours that juveniles exhibit may enhance their ability to survive to adulthood.

These two views are not mutually exclusive; some motor patterns in **altricial** species require a degree of physical development in order to be expressed in their adult form, and some others (for example, bird song in passerines) require practice to reach their adult forms. On the other hand, there is considerable evidence that many of the behaviours that characterize the juvenile period are *not* rudimentary forms of adult behaviour.

This is most clearly seen in the play behaviour of species that produce **precocial** young. Social play and fighting share many similar behavioural components, and it has been suggested that play is a way of practising these specific motor patterns prior to their use in 'serious' contexts. However, play and fighting reliably differ in the sequence of motor patterns, the presence/absence of **vocalizations** and other fundamental features. Moreover, infants of precocial species are often capable of engaging in fighting behaviour in its adult form at the same age at which they are also engaging in social play. In the case of juvenile play it is clear that it is not solely a precursor to adult fighting, and it has recently been suggested that juvenile play has a broad impact on brain growth and development.

P.367

One large class of behaviours seen primarily in juveniles is care-soliciting behaviour. These behaviours may include vocalizations (e.g. the begging vocalizations of nestling birds and infant primates), specific postures (e.g. necks extended upwards with open mouths in nestling birds) and tactile behaviours (e.g. licking of the mother's mouth in infant carnivores and ungulates) that elicit care from other individuals. These behaviours are typically conspicuous and repeated. Rather than being accurate indicators, they appear to exaggerate the juvenile's need for parental care.

Exaggerated demands for parental care are somewhat paradoxical, since one might predict that the interests of parent and offspring would be in agreement, enabling each offspring to indicate its needs to the parent honestly and subtly. In reality, the interests of parent and offspring are not in perfect agreement because they are not genetically identical. Offspring share only half their genes with their mothers (because half their genome is inherited from their fathers) and roughly half of their genes with each sibling (fewer if they have different fathers). From the perspective of the mother, her available parental resources are best distributed evenly among her present and future offspring. Any given offspring, however, benefits from skewing that investment towards itself and away from its siblings. This

sets the stage for parent-offspring conflict over the allocation of parental resources (**see: Parental behaviour**).

Evolutionary biologists have proposed several different interpretations of the exaggerated care-soliciting behaviours. First, offspring may be increasing their conspicuousness to predators, in effect blackmailing their parents into providing more care in exchange for silence. Secondly, if parents are more likely to feed the offspring with the most obvious solicitations, the exaggerated behaviours may enable one offspring within a brood to out-compete its siblings as they scramble for a share of parental resources. Thirdly, these care-soliciting behaviours may be honest demonstrations of offspring vigour that allow parents to preferentially provide care to those offspring most likely to survive in times of limited resources. While each of these proposed explanations has some empirical support, no single hypothesis adequately explains exaggerated care-soliciting behaviour in all species. This early period of dependency is critical for future survival and reproduction, making it likely that multiple factors have shaped the nuances of the parent-offspring relationship.

The process of **domestication** has favoured the persistence of a variety of juvenile characteristics into adulthood, a phenomenon known as neotenization. This is most readily seen in domesticated dogs, which exhibit puppy-like behaviours throughout their lives. These include a tendency to show submissive behaviour (in deference to their human companions), a general lack of **aggression** compared with their wild relatives and the tendency to solicit care-giving behaviour (for example, by licking their owners). Another neotenous feature, an extended **socialization** period, is seen in a variety of domesticated carnivores. Most species of wild cat, for example, have only a brief period during kittenhood when they tolerate the presence of other individuals before they become more solitary adults. Domesticated cats, however, more readily coexist with other cats and with humans. While it is unclear whether these juvenile behavioural characteristics were traits that were directly selected for by humans, the persistence of juvenile behaviours has made it easier to maintain these species in close association with humans, contributing to the success of these domestication events.

Juvenile period

The period between infancy and adulthood, which is characterized by significant anatomical, physiological and behavioural changes associated with adaptation to adult life, is referred to as the juvenile period. The length of the juvenile period differs among species and it is usually longer in species with a longer lifespan. In mammals, the juvenile period starts after **weaning**.

> Table of Contents > K

K

K and r selection

K and r selection is a concept used to explain life history variation. Essentially, r-selected species tend to have small adult size, early maturity and produce many small offspring (e.g. many insects). In contrast, K-selected species tend to be large, have delayed and iteroparous reproduction (successive batches of offspring) and produce relatively few, large offspring with greater levels of parental care (e.g. many mammals). This is a continuum, and thus many strategies fall between the two extremes. r-selected populations typically occupy short-lived (ephemeral) environments that are characterized by low levels of resource competition (r-selecting environments). Thus, r-selected species tend to be colonizing species. K-selected populations occupy constant or seasonally predictable environments that are characterized by crowded conditions and intense resource competition. Under such K-selecting environments there are few opportunities for offspring to become established, and thus the best strategy is to invest in offspring quality rather than in offspring quantity.

Kant, Immanuel

The German philosopher Immanuel Kant (1724-1804) is an iconic figure not only for his brand of moral philosophy, *deontological ethics* (from the Greek *deontos*, meaning duty) (**see: Deontology**); his influence on Western thought and civilization is extensive. Kant's *Critique of Pure Reason* (1781) is one of the seminal works in philosophy. In it, Kant lays out his trademark metaphysical view of nature and epistemological accounts. Kant also wrote on aesthetics, natural science, mathematics, religion and, of course, moral and political philosophy.

With respect to his moral philosophy, Kant disliked the kind of consequentialist thinking later to develop within **utilitarianism**. In contrast to utilitarianism, Kant claimed that an action is right not because of its good consequences but because of the intrinsic character of the action itself. Furthermore, moral excellence does not depend on what we do, but on our motives for doing it.

Kant grounds **ethics** in reason alone and believed that reason prescribes/proscribes our moral obligations. He propounded the *Categorical Imperative*, a core feature of which is the *universalizability test*. The central feature of the test is to ask: 'What if everyone does as I do?' If like behaviour cannot be imagined without contradiction and without exception, then the act is prohibitive. Kant's test is often likened to another deontological account, the *Golden Rule*: 'Do unto others as you would be done by.'

The most famous version of Kant's Categorical Imperative is the *Formulation of Respect for Humanity*, which grounds rights-based ethics: 'Act such that you treat humanity, whether in your own person or in the person of any other, never simply as a means, but always at the same time as an end.' Persons deserve respect because they can chart and bring about their own life plans through exercise of their

reason, and they can be held morally culpable. Their moral significance precedes their instrumental value to others.

For Kant, animals do not have direct moral significance. Instead, Kant held that we can have duties *about* animals or indirect duties *towards* animals. By his thinking, we should regard animals as ‘friends’ of sorts. If we mistreat them, then we are essentially prescribing to mistreat our friends, which is a contradiction in our will.

Killing

It has always been widely accepted that there are circumstances in which human purposes legitimize the killing of animals. Today, few people would object to the veterinary **euthanasia** of severely ill animals. Acceptance of even large-scale killing of animals (e.g. in **culling** and **pest control**) seems to be nearly universal. In most countries, sports involving the shooting of animals are legal and cause no public outcry, although significant numbers of people object to the practices involved. Most people appear to accept that many animals used in biomedical research are eventually killed. Last, but not least, billions of young and healthy animals are, of course, **slaughtered** in farm animal production. However, attitudes to the killing of animals are developing all the time and differ between persons and cultures. The practice of killing animals to meet human needs is questioned in some Eastern religions (see: **Buddhism, Hinduism**) and has certainly provoked public debate in the West, especially over recent decades.

Growing concerns about animal welfare in industrial farming practices have led to the promotion of **vegetarianism** and **veganism** and to questions about our need, and right, to eat animals at all. Some people seem to believe that the life of an animal has no value in itself, though they would accept that people can value animals, just as they can value (care about) teddy bears and mountains. The main ethical theories invoked in discussions of animal **ethics** seem to agree that living, sentient animals have inherent value. However, they disagree over whether an individual animal, such as a deer, is replaceable. Utilitarians believe that animals are replaceable

P.370

and that the killing of animals can be justified. Adherents of animal rights, on the other hand, claim that the killing of a healthy animal is a violation of its right to life.

Kin recognition

Social recognition (i.e. recognition of individuals or various categories of **conspecifics**) is a necessary basis of living in stable social groups in which individuals communicate and interact. As part of this, kin recognition - that is, recognition of genetically related individuals - has been widely studied, particularly since the work of Hamilton (1964) and his concept of **inclusive fitness**.

The concept of inclusive fitness states that the global fitness of an individual consists of his/her own reproductive success, together with the improvement in **individual fitness** that the individual can provide to related animals. Hamilton's theory, namely **kin selection**, thus suggests that helping one's relatives to reproduce benefits the helper by improving his/her inclusive fitness (proportionally to the genetic proximity of the receiver). This implies that related individuals have to be recognized and therefore makes kin recognition a prerequisite of the kin selection theory.

A large number of behaviours indicative of nepotism (i.e. preferentially helping related individuals), and supporting Hamilton's theory, have been observed across species. Parental investment, alarm calls, greater tolerance during competition, support during social interactions or **grooming**, for instance, preferentially directed towards kin, are discriminative interactions that suggest that these related individuals are recognized.

Nepotism and optimal **mate choice** are usually the two main accepted benefits of kin recognition. With regard to kin selection, being able to recognize one's relatives is clearly adaptive as it facilitates the expression of nepotism by identifying the individuals to whom this behaviour should be directed. Kin recognition can also improve direct individual fitness and be of welfare importance. For instance, recognizing one's own mother increases survival, especially among species in which only the mother takes care of her young. In the context of mate choice, Bateson's (1983) theory of optimal outbreeding hypothesized that kin recognition would prevent **inbreeding** and favour the choice of the optimal mate (i.e. neither genetically too close nor too far).

Mainly since the 1980s have the mechanisms and sensory basis underlying kin recognition been widely studied. The term 'recognition' relates to the cognitive mechanisms (i.e. neural processes) enabling animals to classify conspecifics in different categories, whereas **discrimination** corresponds to the expression of different behaviours towards different individuals. As recognition is not visible, discrimination is therefore usually used to infer it, but it should be noted that the absence of discrimination does not necessarily imply the absence of recognition. In experimental situations, the existence of kin recognition can be assessed through tests based, for instance, on the simultaneous or successive presentation of kin versus non-kin individuals. In the simultaneous choice test paradigm, it is not only the existence of recognition that is evaluated but also the existence of a preference for kin. In any case, kin discrimination is inferred through either the observation of affiliative behaviours (e.g. physical proximity, grooming, **play**) or the absence of **agonistic behaviours**.

Four main mechanisms of kin recognition were first proposed: spatial recognition, recognition genes, direct association and phenotype matching.

Spatial recognition is based on the geographic localization of individuals (e.g. being in the same nest). However, as animals then behave discriminatively towards kin individuals based on environmental cues and not on their individual characteristics, it has been suggested more recently that spatial recognition should no longer be considered a mechanism of kin recognition.

The existence of recognition genes was suggested by Hamilton (1964), who hypothesized that a super-gene or group of genes would code for kin recognition. This theory has been named the 'green beard effect' by Dawkins (1982), and supposes the existence of an innate reference template in the brain. The existence of such genes has been widely discussed, and candidate markers relate to histocompatibility

regions of the chromosome, e.g. the major histocompatibility complex (MHC) and other genes resulting in chemical discrimination.

Direct association and phenotype matching were initially considered as two dichotomous mechanisms until the late 1980s, when Richard Porter suggested the use of the terms 'direct familiarization' and 'indirect familiarization' corresponding to a single mechanism, familiarization. Recognition through familiarization is based on experience and appears to be the fundamental mechanism of kin recognition in many species. During direct familiarization, individuals become familiar as a result of direct contact (i.e. individual characteristics are learned and memorized) and are subsequently recognized.

This mechanism is thought to be the most widely found and has been demonstrated in numerous vertebrates using, for instance, cross-fostering or embryo transfer experiments. Nonkin young raised together then behave towards each other as if they were genetic siblings. In the context of indirect familiarization, individuals that have not been previously encountered are discriminated against based upon their phenotypic resemblance to the subject animal (a process called self-matching) or to one of their relatives with whom the subject is familiar (i.e. phenotype matching). In this case it is not individual but family characteristics (which are reliably correlated to the **genotype**) that are used. It has, for instance, been demonstrated that lambs display evidence of recognizing their twins from whom they had been separated at birth, as well as the twins of familiar partners. It should be noted that the recognition mechanisms cited above are not mutually exclusive.

The neural mechanisms on which kin recognition is based are still not exactly known. It is supposed that the animal builds templates that are memorized and against which a comparison of the characteristics of the individuals encountered can be made. But how these templates are built, where they are stored and how the matching is evaluated remain uncertain, even though some decision-making models have been suggested (Tang-Martinez, 2001).

P.371

Kin recognition depends on learning the phenotypic characteristics of kin individuals. This implies that those individuals have to: (i) wear labels giving information about their individual identity or the family group to which they belong; (ii) be able to perceive their conspecifics' labels and form an internal representation based upon them (i.e. a template comprising the traits of kin individuals) and to which the subsequently perceived labels will be compared; and (iii) evaluate the kinship of the individuals encountered thanks to a decision rule.

Complex phenotypical traits that are, to a certain extent, individually distinctive and will be used for recognition are called 'signatures'. The sensory basis used for kin recognition tends to depend on those that are predominant for communication in the species concerned (e.g. **olfaction** in rodents). Recognition can depend mainly on a single sensory basis or on several. In rodents, for instance, anosmic animals (i.e. those deprived of olfaction) are no longer able to discriminate their brothers from strangers. By contrast, in sheep, several studies have demonstrated that visual as well as acoustic cues and **odours** play a role in twin recognition and that the suppression of only one of those sensory cues does not disrupt recognition.

It has been shown that phenotypic signatures have a genetic basis and can thus indeed be used for kin recognition. However, such signatures, especially olfactory cues, can also be modulated by environmental factors such as the diet or maternal olfactory labelling (e.g. licking in the **cat**), which can then influence recognition. The development of kin recognition, its efficiency and the mechanisms used can also vary depending on several factors such as the learning period (e.g. pre- and postnatal learning), the kin individual's relationship (e.g. mother versus siblings), the **ecology** of the species and whether it shows temporal variation.

Kin selection

The term 'kin selection' is often used synonymously with the term 'indirect selection', but its original definition embraced the evolutionary effects of both parental care and descendent offspring and **altruism** directed at non-descendent kin (i.e. relatives other than offspring). Indirect selection encompasses only the latter. This definition recognizes that the evolutionary consequences of a parent helping a descendent offspring are in fact genetically identical to the 'parent' helping a full sibling. Thus kin selection is a process in which genes may increase in frequency when bearers help close relatives produce additional offspring, so long as the benefits of giving aid to relatives outweigh the genetic costs of giving up the chance to produce descendent kin themselves (i.e. Hamilton's rule is obeyed; **see: Inclusive fitness**).

(PE)

Kinship

Animals may benefit from behaving preferentially towards their kin, and this simple insight has revolutionized the study of animal behaviour. One solution to the apparent paradox of altruism is that animals benefit not only by obtaining direct fitness, but also by helping relatives obtain fitness (**see: Kin selection**). Because relatives share genes, helping kin can help spread an individual's genes. This insight, solidified by the evolutionary biologist W.D. Hamilton, created the important aim of quantifying kinship.

Kinship, the probability that genes are identical by common ancestry, can be calculated from detailed genealogies or from molecular techniques that focus on estimating those identical alleles shared by descent. In diploid organisms, the sperm and egg each contain a single strand of DNA that are combined during fertilization and first expressed in the **zygote**. Because each individual in a litter or clutch obtains half its DNA from its mother and half from its father, parents and offspring have a coefficient of relationship (often abbreviated *r*) of 0.5. Within a litter, the exact genes passed on to an individual are likely to be different, but the coefficient of relationship between full siblings is 0.5. Grandparents and grandchildren similarly share a 0.25 coefficient of relationship, while first cousins have a 0.125 coefficient of relationship.

A general method of calculating the coefficient of relationship is to draw a genealogy and then sum the pathways by which two individuals could share genes. Each generational link is counted, and $r = \frac{\text{number of pathways}}{2^L}$, where L is the number of generational links.

Knowledge

Knowledge refers to that which is known; but the basis on which we know, as opposed to simply believe in, something is a source of considerable debate among philosophers. The philosophical study of knowledge is called **epistemology**.

(DSM)

Kwashiorkor

Kwashiorkor is a type of malnutrition thought to be caused by insufficient protein consumption. It usually affects younger animals, especially when switching from a high-protein milk diet when nursing to a high-carbohydrate and -starch diet after weaning, and is most prevalent after famine or when the majority of the diet is uncharacteristically made up of starchy vegetables. Kwashiorkor is characterized by a swollen abdomen, alternating bands of light and dark hair and weight loss.

Laboratory animal

A variety of animals are used in research and, when confined in a laboratory for research purposes, are termed by the species or generic name 'laboratory mouse/rat/dog', etc. In the UK, where good statistical data are collected, approximately 85% of laboratory animals used in research in 2004 were **rodents** (mice (67%), **rats** (18%), **guinea pigs** and other rodents (2%)); 6% fish; 4% birds; 2% other mammals (e.g. **rabbits**, **dogs**, **cats**, primates, **ferrets**, **pigs**, **equids** (**horses** and related species) and ruminants (**sheep**, **goats**, **cattle**, **deer**)); and 1% **reptiles** and **amphibians**.

Laboratory study

A laboratory study is a research project carried out on a **laboratory animal**. This may involve an animal specifically bred for the purpose or the importing of an animal into the laboratory environment. Studies using wild-caught animals may be conducted in the laboratory instead of in the field for scientific or practical reasons; for example, there may be a requirement for close monitoring or a controlled environment where single variables can be changed, in order to allow specific research questions to be answered. Laboratory studies and **field studies** have different implications for the health and welfare of the animal, all of which should be taken into account when deciding whether individual projects are justified. Special welfare considerations are necessary when considering the use of wild-caught animals in a laboratory study (see Table L.1) especially in relation to identifying areas where trapping, housing or techniques will need to be refined.

Table L.1. Welfare issues associated with the use of wild-caught animals in the laboratory versus the field.

Laboratory studies

Field research

Individuals are temporarily or permanently removed from the field - could impact on other animals of same or different species	Presence of researchers or study itself could have adverse effects on other individual animals or ecosystem
Animals will need to be transported to the laboratory - transport is a highly potent stressor, even for purposebred animals	Can be difficult to balance minimizing animal holding time with ensuring that animals are fit for release, not distressed and/or drug residues are at acceptable levels
Laboratory environment is unnatural, impoverished and extremely stressful for wild-caught animals - severely reduced opportunities for performing natural behaviours, e.g. foraging, exercise, socialization	Animals are in their own environment, which may also speed recovery from capture stress and use in procedures
Veterinarian should be on site or on call, to treat animals and advise users and care staff	Veterinary resources could be remote
More opportunities for regulators to supervise researchers	Reduced control and supervision of researchers
Risk to the welfare of other animals in the unit if pathogens introduced; quarantine periods add to captivity time	Compromised health, welfare and fitness may be hard to predict and detect, including long-term effects, e.g. impacts of marking and external instrumentation still not fully understood
In less commonly used species, may be little or no expertise on housing, care, analgesia, etc.	Acceptable standards of anaesthesia, analgesia and asepsis are harder to maintain during field surgery
May require fewer animals since conditions are controlled, experimental animals cannot be lost	If recapture is necessary, animals will experience additional stress
Animals can rapidly lose condition and/or learn inappropriate behaviours, e.g. tameness; may have to be rehomed or killed rather than released	Animals should retain fitness, post-study release more feasible

Lactation

Lactation, the secretion of milk from specialized mammary glands, is one of the major distinguishing characteristics of the taxonomic class mammals. The production of nutrient milk is thought to have evolved from secretions of apocrine-like glands associated with hair follicles, which may have provided moisture and anti-microbial agents to parchment-shelled eggs of pre-mammalian species.

In all cases the mammary glands are located ventrally in pairs lateral to the midline. However, there is considerable variability both in the number of glands and in their location along the midline. Glands may be located in any, or all, of the thoracic, abdominal or inguinal regions; species with small numbers of offspring such as ruminants and horses have between two and four glands in the inguinal region, whereas others such as primates have a single pair of glands in the thoracic region.

Species with multiple litter sizes - e.g. many carnivores, rodents or pigs - have between six and 16 glands arranged in pairs spread across all three regions. For most species both males and females have mammary glands but in males they are rudimentary in structure, lacking the post-pubertal development seen in females and are non-functional. In some species males may lack external teat structures and, in other cases, glandular tissue may be completely absent. There are, however, many anecdotal accounts of lactating males and it seems clear that, given appropriate endocrine support, males of a number of species can achieve a functional lactation state. There is at least one well-described exception to this rule, the Dayak fruit bat (*Dyacopterus spadiceus*), where both sexes lactate and share feeding of the offspring.

While there is a large degree of variability in the number, position and external appearance of the mammary glands, the internal structure of mammary tissue does not vary much between mammals. The functional unit of the gland is the alveolus, a small, sack-like structure with a single layer of secretory epithelial cells surrounded by a layer of contractile myoepithelial cells and a connective tissue basement membrane. Milk is synthesized and secreted by the epithelial cells into the lumen of the alveolus before being squeezed into a duct system by contraction of the myoepithelial cells under the influence of **oxytocin**. Alveoli are arranged into lobules consisting of 100-200 alveoli contained within a connective tissue sheath. A contractile duct system collects milk from individual alveoli and lobules and conveys it to the external teat. In mammals producing a large volume of milk, ducts may lead into large, open cisterns allowing for greater milk storage.

Milk production is not a continuous process in mammals, its onset being timed to coincide with **parturition**, and it continues for as long as nutritional support is required by the offspring. The attempted termination of suckling by the mother versus the persistence of the young can be viewed as the product of within-species evolutionary conflict. Lactation is energetically expensive, and the mother aims not to invest more than is necessary to maximize her **fitness** (i.e. the best strategy is not to give more milk than is necessary to ensure the survival and optimal development of the young). By contrast, suckling is a very efficient way of obtaining nutrients for the young, and so the offspring maximizes its fitness by being dependent upon milk and persisting with suckling for as long as possible. The demands of the two are therefore in conflict, and an optimal **weaning** age for a given species emerges as a result. None the less, the process of weaning may see quite aggressive behaviour being exhibited by both the mother and her offspring towards each other. It has been suggested that this is also an important time of emotional development in the young, as they learn to cope with **frustration**.

Mammals will undergo a series of reproductive cycles, each accompanied by a period of lactation, and therefore mammary tissue may undergo a number of repeated cycles of growth and differentiation, followed by active milk production and then involution and regression. The maintenance of lactation once established is termed galactopoiesis and is regulated by two interrelated factors, the presence of galactopoietic hormones and the continued removal of accumulated milk. The two most important regulatory hormones for lactation are the pituitary hormones oxytocin and **prolactin**, or leuteotropic hormone (LTH). Inhibition of galactopoietic hormones will depress milk production, depending on the species and lactation stage; however, milk removal is the major factor in maintaining secretion. As milk components accumulate in the alveolar lumen, a feedback inhibitor of lactation is secreted from the alveolar epithelial cells and blocks further milk secretion from the epithelial cells. Removal of milk by suckling (or by **milking**) removes the inhibitor factor and allows for continued milk secretion. Galactopoiesis continues up to weaning when, with the suspension of suckling (**see: Nursing**), the mammary gland involutes and the cycle will start again only with a new pregnancy. The relationship of lactation to the overall reproductive cycle varies, with many species exhibiting a lactational anoestrous period, where oestrous cycling is suppressed during early lactation. This anoestrous period can be used by livestock producers to manage reproductive performance. For example, in the sow oestrus first occurs several days after removal of the piglets, so weaning is used to synchronize oestrus, and therefore to synchronize the subsequent farrowing.

Yield and composition of milk also vary considerably between and within species, and with the stage of lactation. Milk contains three main components, carbohydrate, protein and lipid, suspended in an aqueous medium. Carbohydrate is principally supplied by the disaccharide lactose consisting of a β -1,4-glycosidic linkage of D-glucose and D-galactose. Lactose is unique to mammalian milk and is common to almost all mammals, and is digested by the specific neonatal enzyme lactase, cleaved into glucose and galactose, which is subsequently converted to glucose. In addition to its nutritional role, lactose is the major osmolyte in milk responsible for drawing water into the alveolus. Water is by far the largest component in milk, forming 87% in cow's milk.

Milk contains two unique families of proteins, the caseins (caesins) and the whey proteins. Caseins are synthesized by mammary epithelial cells and are easily digestible proteins providing a good amino acid source for the neonate. Some

P.375

caseins are at least in part responsible for the soporific effect of milk in the young, but the change in gastric digestive enzyme (increase in gastric trypsin) with age eliminates this effect in the adult. None the less, gastric-protected formulations can be made, which can be used to calm animals. The whey proteins consist of the lactalbumins and lactoglobulins, which are again specific to mammalian milk. Triglycerides make up the major lipid component of milk. Milk fat is utilized by the neonate to form adipose tissue, but is also metabolized as an energy source. The lipid component is the most variable component between

species, with marine mammals having fat contents of up to 60%, while fat content is negligible in, for example, early lactation in marsupials. Lipids are secreted as fat globules bound by a lipid bi-layer, and are present as an emulsion in the aqueous phase of the milk.

Composition of the milk changes throughout the lactation period, adapting to meet the specific needs of the developing neonate. Of particular importance is the milk produced in the first few hours postpartum, which is termed **colostrum**. The mammalian neonate is generally immunologically competent but naive. Humoral immune protection, in the form of immunoglobulin, is supplied by a process of transfer of passive immunity from the mother to the neonate. This generally occurs by transfer of maternal serum IgG from the mother to the offspring either *in utero* or, after birth, by ingestion of immunoglobulin-rich colostrum by the neonate. These maternal immunoglobulins offer immediate immune protection prior to the establishment of a fully functioning **immune system** in the neonate. The immunoglobulin content of the colostrum rapidly declines in the first 12 h following parturition and, at the same time, the neonate's ability to take up the immunoglobulin proteins also reduces in the process of gut closure.

The mammalian newborn exhibits a well-developed suckling behaviour, using thermal, olfactory and textural gradients to locate the teats on the mother's ventral surface with its nose and tongue. Contact with the teats triggers a strong suckling response. Suckling stimulates the release of oxytocin in the maternal system which, in turn, promotes milk letdown. Release of milk may be further stimulated by behaviours such as butting at the udder seen in some ruminants or by the treading response that kittens may perform while suckling. Species with few, precocious young such as ruminants and horses will suckle standing, while those with large litter sizes and more immature young will lie down to suckle.

Lairage

Lairage generally refers to the period of time and/or accommodation in which animals are held, usually off-vehicle, during a period of transportation, or at an abattoir prior to slaughter (**see: Slaughter; Slaughterhouse; Transport**). Lairage is important because it provides the animals with an opportunity to recover from the physical and psychological **stressors** associated with transportation, whether this is prior to slaughter or part-way through a journey. In many countries there is legislation governing maximum journey durations and, thus, the timing and duration of any lairage during transportation. At the abattoir some lairage time is inevitable, given the logistics associated with receiving and scheduling animals for slaughter, and in some countries a rest period before slaughter is mandatory. However, despite these regulations, there is still uncertainty and debate about the appropriate timing and duration of lairage, and the ways in which animals should be managed during it.

From a purely meat quality perspective, the evidence suggests that, except when animals are severely stressed, lairage prior to slaughter should be kept to a few hours (**see: DFD meat**). The effects of pre-slaughter lairage will vary depending upon pre-slaughter muscle glycogen levels, which, in turn, are influenced by a variety of factors, such as the gender and character (**temperament**) of the animals, nutritional history, the length of time off food and water, the duration of transportation and the ways in which the animals have been handled. If glycogen concentrations are above the critical threshold (40-57 $\mu\text{mol/g}$ for **cattle**), then there may be little benefit in having a long lairage period, although there is some evidence that improved meat quality may be obtained with supra-threshold glycogen levels.

A rest period of less than 12 h in lairage reduces DFD meat in bulls and, perhaps, also in cattle that have been minimally stressed pre-slaughter. Lairage times of 3-4 h may also improve other aspects of beef quality as well as eating quality (texture and flavour) of beef from animals that have been minimally stressed pre-slaughter. There is some evidence that these improvements may be related to the shorter

than usual fasting periods. It must be remembered that any reduction in fasting and lairage time may have adverse consequences for food safety; animals will have increased ruminal volume at slaughter and this may increase the risk of rupture and carcass contamination during processing.

It may be argued that immediate slaughter is desirable from an animal **welfare** perspective, but given that this may not be achievable and that delays will occur, an extended pre-slaughter lairage period may allow animals more time to rest and recover from the various stressors associated with transportation to the abattoir. Studies with **sheep** have shown that plasma cortisol levels decline during lairage of a few hours' duration. However, the possibility for recovery is likely to be highly dependent upon the design and management of facilities. Animals in abattoir lairage are in a novel environment, may be mixed with unfamiliar animals and are exposed to different handlers and feeding and watering regimes. Such factors could add to the stress resulting from transportation. Studies have shown that animals are less likely to rest with increased human and other animal activity in the lairage facility, and when stocked at lower **space** allocations and/or larger group sizes. There is some evidence that it takes 2 or 3 h before some animals (sheep and cattle) will settle down and begin to rest in pre-slaughter lairage, and a lairage period of about 10-15 h is required to allow animals to recover from the effects of food restriction and transportation.

Evidently, the latency to rest and the time to recover will depend upon transportation duration and the degrees of fatigue, thirst and hunger it may induce and, thus, motivation to rest, drink and eat, if water and food are available. Work has shown that cattle penned without feed after a short period of transportation do not drink immediately, but drink during the subsequent 6 h. However, cattle transported for long periods (about 24 h) all drank immediately after they were unloaded,

P.376

and the longer the period without water, the more they drank when given the opportunity. Thus, depending upon total time that the animals have been deprived of food and water, and how long they will be held in lairage pre-slaughter, food and water may need to be provided. However, the issue of gut-fill and potential for carcass contamination needs to be considered.

There are reports that increased time in lairage can result in increased bruising, which has detrimental effects on both carcass quality and animal welfare. The incidence of bruising will also depend upon the quality of the facilities and management - for example, whether animals are repeatedly disturbed and if groups of unfamiliar animals are mixed, resulting in increased levels of agonistic interactions.

In some countries there are requirements to break journeys that extend beyond a specific duration. These breaks can be for as little as 1 h, during which time the animals must be given food and water. Studies with sheep have indicated that it is inadvisable to provide feed and water on the vehicle during a stop because of aggressive interactions between the animals, such as riding and trampling. Also, the mechanics of providing food and water on board the vehicle make it impractical. Consequently animals must normally be unloaded into yards or pens and then re-loaded after feeding and watering. Short rest breaks of a few hours are likely to be insufficient to allow any real recovery from transportation, particularly as the animals will be entering a novel environment. Furthermore, studies on sheep have shown that they are primarily interested in feeding following journeys and are not motivated to drink until 2-4 h after feeding. Consequently, if provided with only a short break during a journey, they do not have time to drink and this could result in the development of negative water balance during the remainder of the journey, with the outcome that animals are dehydrated at the end of their journey. It has been recommended that sheep require a journey break of about 6 h if they are to have sufficient time to eat, drink and rest.

The implications for welfare of the additional handling associated with unloading and loading animals is a key consideration for determining breaks during transportation. Research with sheep has shown that loading leads to elevated cortisol levels and **heart rates**, which are sustained for the first few hours of

travel, indicating that the procedure is stressful for the animals. When the sheep were loaded a second time, the cortisol response was attenuated, suggesting that, perhaps, the initial response was to novelty rather than the loading procedure per se. The degree of **stress** associated with unloading and loading will depend upon the quality of **handling** and the facilities and, in some instances, it may be better for animal welfare to continue the journey to completion than to break it for a short period if animals have to be unloaded and reloaded.

Lameness

Lameness describes a multitude of conditions, including foot problems, musculoskeletal problems and joint problems, that can hinder or inhibit normal **locomotion**. Lameness occurs in all species and, in some species, causes significant economic and **welfare** effects. In farm animal species, lameness and/or musculoskeletal problems is the second most common cause for **culling** in **pigs** and the third most common cause for culling in dairy cows. The causes of lameness can be traced to four main factors: **housing**, hygiene, genetic selection and nutrition. Different housing systems can influence the amount of physical trauma to the body and the feet - either directly by perhaps including physical aspects such as rough flooring or poorly maintained slats, or indirectly by perhaps increasing the amount of time that animals spend standing. Clean, hygienic facilities help in inhibiting the spread of infectious bacterial and viral diseases such as **footrot** and infectious arthritis. Genetic selection for increased mature body size or for growth/production rate is believed to be a primary culprit for the increased prevalence of lameness in recent history, particularly in broiler **chicken** and pig production. Nutritionally unbalanced diets can cause deficiencies of nutrients such as calcium, which will affect **bone strength**, and overfeeding may result in overweight animals, which are more susceptible to **laminitis** and have an increased risk of overloading musculoskeletal tissue.

Lameness is considered to always be painful, and can inhibit normal functioning and decrease welfare. Lameness is known to activate **stress** responses in animals, increasing concentrations of hormones such as cortisol in the blood. Cortisol is a **glucocorticoid** that is a primary stress response hormone that acts to counteract the stress, but it can have both positive effects (blocking inflammatory reactions) and negative effects (decreasing immune cell populations, which can lead to infection).

As mentioned, genetic selection for increased production is believed to have increased the incidence of lameness. Studies have shown that the fastest-growing animals and animals that are overweight have a higher incidence of lameness than animals of normal weight and animals with a slow **growth rate**. Increased production output, specifically in reproducing animals, has also shown an increase in lameness when compared with animals of lower production rates. Animals bred for a specific conformational trait have also exhibited higher incidences of lameness, particularly in the form of hip dysplasia and other related conditions. It has been suggested that selection for high growth and production rates has

negatively affected bone strength. Decreased bone strength can lead to conditions such as arthritis, osteoarthritis and fractures, all resulting in lameness.

In some cases, early identification of lameness may increase the chances of recovery. Identification of lameness primarily depends on observations of **posture** and **gait**. In general, identification of a change in gait characteristics (length, fluidity) or in postural equality (all limbs weighted evenly when standing) is the first sign of lameness. Behavioural measures can also indicate problems, e.g. when eating behaviour and willingness to stand or move have decreased.

As mentioned, all species are susceptible to lameness and, although it occurs in different forms, there are two general categories into which lameness falls.

P.377

Foot lesions and problems

Laminitis

Laminitis is a common disease of the foot or hoof that is typically a result of unbalanced feeding, excessive weight, and environmental or production stress. Small blood vessels between the bone and the laminar structures in the foot become blocked by **inflammation** or rupture, causing discoloration to the hoof. This inflammation or rupture of the vessel causes the horn to become soft, allowing ulcers of the sole to emerge in the horn. In severe cases, the bone and hoof can separate.

Foot-and-mouth disease

Foot-and-mouth disease is a highly contagious viral disease that affects a wide range of species. Symptoms include blisters and sores around the foot and mouth, and lesions on the teats or udders.

Footrot

Footrot is an infectious disease caused by the intestinal bacterium *Fusobacterium necrophorum*, which is shed in the faeces. The bacteria cause necrotic lesions in the soft tissue between the claws, resulting in swelling. If footrot goes untreated, the infection can spread to the upper leg.

Trauma

Trauma to the feet from the environment can also cause bruising and lesions of the horn. **Pain** is thought to be associated with these conditions and can cause a noticeable change in gait, posture or behaviour of the animal.

Bone and joint problems

Osteoarthritis

Osteoarthritis is a form of arthritis that is common from age-related wear and tear or as a result of injuries. It mainly affects synovial joints, specifically in the limbs. The articular cartilage degenerates over time and the bone becomes thickened and distorted, restricting movement of the joint. Inflammation of the joint and pain are associated with the condition, and symptoms can be aggravated by excessive weight. Osteoarthritis is more common in older animals but can occur due to injury in young animals as well.

Osteochondrosis

Osteochondrosis has multiple forms, is prevalent in young, growing animals and is a primary cause of lameness in several species. In osteochondrosis, there is a failure of epiphyseal growth cartilage to form into bone because of necrotic tissue in the area. When lesions are large enough, the necrotic tissue will protrude into subchondral bone (*osteochondrosis manifesta*). In severe cases the articular cartilage may collapse, forming a cleft into the subchondral bone (*osteochondrosis dissecans*) causing inflammation and osteoarthritis. Epiphysiolysis, another form of osteochondrosis, is the loosening or separation of the epiphysis from the shaft of a bone.

Mycoplasma

Mycoplasma arthritis occurs in young animals and is caused by a respiratory infection with *Mycoplasma hyosynoviae*. It is prevalent in the majority of herds, even though there are no clinical signs of infection. The organisms can be found in the upper respiratory tract in animals of all ages, but the infection affects only young animals. The infection primarily affects the joints and tendon sheaths around the joints, but it can also cause pneumonia, **mastitis**, vaginitis and abortion. Clinical signs include a reduction in normal behaviour, including feeding behaviour, and a slightly elevated temperature. *Mycoplasma* arthritis is more common in heavier animals. *Mycoplasma* species lack cell walls, making treatment difficult due to antibiotic resistance.

Osteoporosis

Osteoporosis is characterized as a loss of integrity of trabecular bone and thinning of cortical bone. Osteoporosis is common in postmenopausal women and is associated with calcium deficiency and decreased **oestrogen** concentration. Osteoporosis can affect older animals of other species as well. After maturity, bone strength starts to decline and, if optimal bone strength was not reached during adolescence, the risk of osteoporosis increases. Osteoporosis may also occur in animals under high reproductive stress. **Gestation** and **lactation** place high calcium demands on the animal, sometimes depleting bone calcium reserves. Over time, if these reserves are not replaced due to chronic stress, osteoporosis may develop. The effects of osteoporosis are typically irreversible, and the onset of the disease causes an increase in fracture rate.

Fractures

Fractures can be a result of physical trauma or from one of the conditions listed above, such as osteoporosis or osteochondrosis. Presence of fractures will cause the animal to be unable to bear weight on the affected limb and have a reduction in activity.

Laminitis

Laminitis is a non-infectious disease of the hoof caused by an **inflammation** of the laminae. Between the hard outer horn of the hoof, the sole and the pedal bone is a cushioning layer of tissue known as the corium. Within the corium are the laminae, which are layers of sensitive tissue that are arranged vertically from the top of the hoof to its base, both acting as shock absorbers and producing the hard, keratinized tissue of the wall and sole. The inner, or dermal, laminae are stationary and, along with other connective tissue, hold the pedal bone in place within the hoof. The outer, or epidermal, laminae are connected to the hoof wall and migrate past the dermal laminae as the hoof grows from the coronary band. Connections between these two layers of laminae maintain the general structure of the hoof by acting as a bond between bone and hoof wall. These connections are continually broken and

P.378

renewed as the epidermal laminae migrate downwards with the growing hoof, the whole process being controlled by locally produced enzymes, enzyme activators and enzyme inhibitors. Damage to the blood supply to the laminae or an imbalance of enzyme activators and inhibitors can result in laminitis.

Different phases of the disease are characterized by specific clinical signs. The most severe phase is acute laminitis, and this is often associated with a nutritional imbalance known as acidosis. Acidosis occurs when carbohydrate intake is rapidly increased compared with fibre intake, e.g. with unrestricted access to spring grass, high-concentrate postpartum rations or if food particles are so small that they inhibit chewing behaviour. For example, food particles shorter than 1.7 cm inhibit cud chewing in dairy cows. This, in turn, reduces the amounts of saliva and, more crucially, bicarbonate that are naturally produced during the chewing process. The bicarbonate plays a vital role in controlling ruminal acidity by acting as a buffer and, to maintain a normal ruminal pH above 6, the cow will need to chew for around 10 h each day.

When acidosis occurs, toxins are released into the bloodstream and become concentrated in the blood vessels within the laminae of the hoof, disrupting the blood supply and causing inflammation. The dermal-epidermal interface becomes damaged and cell death (necrosis), along with blood leakage (haemorrhage), occurs, and the affected area becomes swollen (oedema), further reducing blood supply. This oedema causes severe pressure between the hard hoof wall and pedal bone, resulting in intense pain. Immediate clinical signs of acute laminitis are sudden, severe **lameness** with no visual changes in hoof structure, though the affected hoof may be warmer than usual. The haemorrhaging of the corium during acute laminitis can reduce or even halt new horn growth.

Subclinical laminitis is a phase of the disease that can result from structural damage caused by either acute laminitis or physical injury. Prior to the onset of lameness, subclinical laminitis can be detected by the yellow discoloration of weak horn growth. Hoof tissue that is damaged during acute laminitis produces poor-quality, abnormal horn growth and, as a result, the wall and sole of the hoof become softer and more easily damaged. As the hoof becomes weaker, an animal is more likely to sustain secondary foot problems such as bruised soles, abscesses, ulcers, white line disease, heel erosion and cracks in the hoof wall. Indeed, lameness is often caused by these secondary problems rather than by the subclinical laminitis itself. In advanced cases, the pedal bone may begin to separate from the hoof wall as the laminae and connective tissue break down. As a consequence of the separation of the laminae, the pedal bone may rotate downwards, compressing the base of the corium and causing severe pain. Hoof horn surrounding inflamed or infected parts of the hoof tends to grow more rapidly during the subacute phase, leading to misshapen feet and, consequently, altered conformation. An animal suffering from lameness due to laminitis will place more of its body weight upon healthy hooves, and so displays a characteristic hunched standing position as an attempt is made to keep as much body weight as possible off the affected feet.

The third form of the disease is chronic laminitis, in which the hoof horn is also produced at a greater rate than healthy horn. If the disease remains untreated the internal structure of the hoof and its blood supply will continue to break down until the damage sustained is irreversible. Over time the pedal bone may penetrate the sole of the hoof.

Many factors have been implicated as contributing causes of laminitis, and these include poor nutritional management (e.g. acidosis) and excessively hard ground (**see: Flooring**). Horses performing fast or prolonged work on hard surfaces may develop concussive laminitis, particularly if their hoof horn quality is already poor. Similarly, hard lying areas discourage dairy cows from lying down, and excessive standing may predispose these cows to laminitis.

Many internal and environmental factors related to laminitis are associated with **parturition**. In dairy cows, most incidences of lameness occur within the first 3 months after parturition, and contributing factors can include **stress** during parturition, metabolic disorders, too little exercise and **mastitis**. Metritis, or retained placenta, can also cause laminitis in both mares and cows.

Prevention of laminitis includes: (i) avoiding excessive working or housing of animals on hard surfaces; (ii) providing comfortable bedded areas for all animals to be able to lie down together; (iii) avoiding malnutrition, including obesity; (iv) allowing animals to exercise; and (v) keeping stress levels to a minimum, especially during the period surrounding parturition. Further measures include introducing animals to elements of a new environment before it becomes permanent. For example, dairy heifers are often maintained in loose-straw yards but housed in cubicle yards when brought into the milking herd. Exposure to the cubicle yard prior to entering the herd will allow the heifers to learn how to enter and lie down in the more regimented cubicle system, encouraging optimum lying behaviour when they subsequently enter the herd.

Language

The term 'language' is generally used to refer to systems that play a role in **communication**, such as computer language, dolphin language and human language. In the 17th century, **René Descartes** reasoned - contra Montaigne - that even though parrots may produce the same sounds that we make, such sounds cannot be called language. According to Descartes, parrot sounds are not produced to express thoughts, but are based on 'passions', such as a desire to obtain food or to satisfy other needs. The issue of whether or not animals have language is still debated today. For example, Savage-Rumbaugh *et al.* (1998) claim that Kanzi, a laboratory-reared bonobo (*Pan paniscus*), has language skills that are comparable to a 2.5-year-old child. However, as pointed out by, for example, Kirby (2000) in a review of this work, much of such a claim hinges on how key aspects of language are defined.

In order to evaluate whether animals have language, whether human and animals systems of language have similar or unique features, or whether there is any evolutionary overlap between human language and animal systems of communication, it is

P.379

necessary to define the concept of language more precisely. Hockett (1960) lists 13 features that characterize human language, for example that human language is made up of discrete units, that its **signals** are arbitrary (there is no relation between the form of the signal and its meaning), productive (novel meanings can be created), rapidly fading (signals do not persist after being produced) and show dual patterning (small units can be combined into different possible orders to form larger units).

Even though Hockett's features have been used to compare human language and animal communication, these features have no formal definition, and many interpretations of, for example, creativity in language have been possible. Chomsky (1986) defines language more formally as the internal representational system of knowledge that makes it possible for humans to map signals to meaning by using syntax. In its broadest possible scope, this system of knowledge involves knowledge of the sound structure of language (phonology) or, in the case of sign language, knowledge of the sign patterns of language, knowledge of the ordering of signals in relation to each other (syntax), knowledge of the internal structure of words or gestures (morphology) and knowledge of the semantic-conceptual structure of language (meaning) (Jackendoff, 1996, 2002). Each of these knowledge systems is characterized by a finite set of primitives (for example nouns, verbs and adjectives in the case of syntax) and sets of rules or constraints that define how such primitives can be combined. This allows for a more precise definition of, for example, the concept of creativity in language (see below). This entry will not focus on sign language any further, but it will examine the properties of each knowledge system described above in human language, and briefly consider whether animal systems of communication share any of its features. Subserving human knowledge of sound structure are the mechanisms of speech perception and speech production. These mechanisms are considered first.

Liberman's Speech is Special (SiS) hypothesis argues that human speech perception is different from sound perception in animals (e.g. Liberman, 1996). Pinker and Jackendoff (2005) argue that this hypothesis is supported by, among other things, research on the categorization of sounds. Kuhl (1991) shows that adults and 6-month-old babies judge a particular 'i' sound to be more similar to a prototypical 'i' sound compared with a sound at the periphery of the 'i' sound category, even though the physical distance is the same in both cases. Rhesus monkeys do not display this perceptual magnet effect - a bias towards the prototype of the vowel category. However, Hauser *et al.* (2002) and Fitch *et al.* (2005) advocate a null hypothesis: that, until there is clear evidence to the contrary, there should be considered no differences between sound perception in humans and animals. In order to support their view, the above authors cite evidence that shows parallels in speech perception between humans and closely related primates. For example, both newborn humans and cotton-top tamarin monkeys appear to be able to discriminate between two unfamiliar languages (Dutch and Japanese) (Ramus *et al.*, 2000); these authors attribute this ability in both species to general processes of the primate auditory system. Hauser *et al.* (2002) and Fitch *et al.* (2005) claim that any differences between humans and animals regarding speech perception - such as those presented by Pinker and Jackendoff (2005) - are not relevant to the language faculty.

With respect to speech production there seems to be agreement that there are qualitative differences between humans and non-human animals. One of the most characteristic properties of human speech is the period of babbling that infants go through when they are around 5-7 months of age. During this phase children show a strong bias to imitate the sound patterns of their mother tongue, although they do not do this for other environmental sounds. In fact, deaf children appear to babble with their hands. The innate drive - but also the capacity to imitate sounds that are made by **conspecifics** - is absent in animals such as **chimpanzees**, which are evolutionarily close to us. An imitative capacity has been found in unrelated species, such as in certain dolphins and songbirds. However, despite many parallels between humans and

songbirds in how sound production is learned, it seems that more is prespecified for songbirds when they learn their repertoire compared with humans, as evident in learning preferences and isolate songs (Doupe and Kuhl, 1999).

Human knowledge of sound structure consists of knowledge of a finite set of the smallest building blocks of sounds (phonemes) for each language (for example, 44 for English), in addition to a rule system that combines phonemes into syllables and then words. Pinker and Jackendoff (2005) argue that phonology is uniquely human; that the combinatorial properties of phonology have no analogue in evolutionarily related primates, although there may be such analogues for dolphins and songbirds (for the latter of which there is, for example, evidence of the use of syllables; see Doupe and Kuhl, 1999). Unfortunately, this area of language is not yet well enough researched even to approach the beginnings of an overview.

Knowledge of syntax consists of many different elements that together result in the ordering of words in relation to each other. Pinker and Jackendoff (2005) list four elements. The first element is the hierarchical or recursive structure of the strings of words and phrases that together form sentences. Recursion or recursive embedding is the insertion of a pattern (such as a sentence) into the same pattern (another sentence) (see, e.g. Jackendoff, 1993). For example, inserting the sentence 'John fears Peter' into the sentence 'Mary thinks X', where X stands for another sentence, thus results in 'Mary thinks John fears Peter'. This process is recursive in that there is no limit to the number of insertions: for example, 'Carl hopes that Mary thinks John fears Peter', 'Zoe assumes that Carl hopes that Mary thinks John fears Peter', etc. Recursivity formally defines creativity in human language.

The second way in which syntax manifests itself is in the form of a parameter that specifies which words in both small and large composite strings (phrases and sentences) in a particular language generally come first. For example, if a phrase has its main element (such as a preposition in a prepositional phrase) first, then this is also likely to be the case for verb phrases, adjectival phrases, etc. in that language. The third element that constitutes syntax is agreement, the way in which verbs and adjectives are marked with inflections corresponding to number, person, grammatical gender or other features of related nouns. The fourth element that impacts on word order is case: case marks noun phrases with

P.380

inflections (nominative, accusative, dative, genitive, elative, ablative, etc.) depending on the grammatical role of the phrase in relation to a verb, preposition or another noun.

There seems to be general agreement that animals do not possess the ability to form strings that have recursive or hierarchical properties. However, Jackendoff and Pinker (2005) and Pinker and Jackendoff (2005) stress that human languages can differ in the relative contribution of each of the four elements mentioned above, with, for example, Pirahã lacking recursivity (see Everett, 2005). Comparative research in relation to the other three elements that are part of human syntactic knowledge is currently not available.

It has been widely observed that there are qualitative and quantitative differences in word learning between humans and animals (Hauser *et al.*, 2002; Fitch *et al.*, 2005; Pinker and Jackendoff, 2005). For example, animals do not have words for abstract entities such as 'yesterday', and are not able to acquire the same number of words (50,000-100,000) in the same effortless manner as do humans. Comparative research relating to knowledge of the internal structure of words (morphology) is rare. An exception is a study by Endress *et al.* (2009), who found that cotton-top tamarin monkeys were able to distinguish between the past tense morpheme '-ed' as either a prefix or a suffix, just as human beings do. More research in this area of language is also required.

Another crucial aspect of human knowledge of language is the semantic-conceptual structure of language, the meaning that we can derive from or put into words. There is no doubt that several concepts related to the properties of language discussed above are absent in other species, such as the concepts of 'recursion' and 'verb phrase'. However, other species have basic knowledge of cause and effect,

navigation and - if part of a social species - knowledge of social structure, even though such knowledge may be structured differently (Povinelli, 2000). If a species has a well-developed system of communication, it should be no surprise to find some of these elements in their messages. However, Pinker and Jackendoff (2005) claim that such abstract concepts as essence (for example, a component of folk chemistry), ownership, multipart tools, fatherhood, romantic love and **ethics** are absent, rudimentarily present or present in a different fashion in other primate species. These predictions have not yet been put to the test.

In conclusion, there is no simple answer to the questions of whether animals have language, whether they have similar or unique features in their systems of communication compared with us or whether their systems of communication evolutionarily overlap with human language. The evidence is dispersed over many areas of knowledge that make up language, and in many cases the evidence is not (yet) there. The search for an answer to these questions, however, is important, since the answers may reveal something about our own evolutionary history, and about the uniqueness of both our and other animals' systems of communication (Hauser, 1996).

Lateralization and handedness

Lateralization of the **brain** refers to structural and/or functional differences between the left and right sides of the brain. As it usually refers to differences between the left and right hemispheres, it is also known as hemispheric specialization. However, there are known forms of lateralization (e.g. control of **sexual behaviour**) that occur at subcortical levels of the brain. Although hemispheric specialization was thought to be a unique characteristic of humans, underlying our abilities of **language** and higher **cognition**, we now know that it is common among vertebrates. Chickens, for example, have highly

lateralized brains; feeding responses that require the chick to discriminate grains from a distracting background

P.381

are controlled by the left hemisphere, and attack responses are controlled by the right hemisphere. The right hemisphere's role in controlling attack responses has also been shown in fish, toads, lizards and gelada baboons. In animals with their eyes placed laterally on the sides of their head, attack responses are manifested as a leftward side bias, since input from the left eye is processed primarily by the right hemisphere. Prey-catching responses are biased rightward, as shown in chicks and toads.

Hemispheric specialization can also be reflected in hand/limb preferences (e.g. many species of parrots use the left foot to hold food), but hand preferences do not always indicate the direction of brain lateralization. For example, rats have a population bias to use the right hemisphere to express emotional behaviour, as do other species, and they also show a population bias in a number of other types of lateralization, but 50% of rats prefer to use the left forepaw to reach for food and 50% the right. The same applies to marmoset monkeys. In these species, left-paw-preferring individuals are more emotional (more fearful) than are right-pawed ones. Hence, the limb preference may reflect which hemisphere is dominant and indicate the **temperament** of the animal. This has implications for the **welfare** of these species, since hand preference could be a useful indicator of responsiveness to stress. In fact, there is some evidence in primates that left-handers show higher levels of cortisol secretion when stressed than do right-handers.

When we consider the range of vertebrate species investigated in studies of lateralization, we can see that there is a general pattern of the left hemisphere being used for considered responses, which may require the animal to inhibit responding while it decides on the appropriate action to perform, whereas the right hemisphere is used when the animal must make a rapid response. In fact, animals are more responsive to an advancing predator when it is on their left side. The right hemisphere is also used in the expression of **emotions** and for processing spatial information. The ubiquity of lateralization among vertebrates, together with some recent evidence for lateralization in invertebrates, leads one to assume that it must be beneficial. Recent evidence shows that lateralized individuals are able to perform two tasks at once, whereas non-lateralized individuals cannot, and that lateralization assists in the formation of long-term memory.

Laying hen housing

Virtually all chicks that are destined to become laying hens are housed, as they need extra warmth and protection from predators. Most adult birds are also housed for at least some of the time. Free-range flocks are invariably confined to houses at night to protect them from predators, but also to encourage them to lay their eggs in nestboxes in the house. Egg laying is a morning activity. Hens will seek the shelter of their house in cold, wet weather or to avoid bright sunlight. The majority of laying hens are housed intensively in climate-controlled housing to increase output and productivity per unit area and to reduce overhead costs. Intensification requires more sophisticated management and housing systems in order to control most of the variables that affect productivity, including temperature, humidity and air quality, plus feed and water quality and availability. See Weeks (2002) for more details.

Enclosure and artificial ventilation enable control of light. The intensity, duration, spectral composition and photoperiod of light profoundly affect the maturation of pullets, onset of lay, egg size and numbers and bird behaviour, and are thus extremely important considerations in hen housing (see Manser, 1996 for a review). The spectral sensitivity of poultry differs from that of humans, and hens have four rather than three different types of cones within their retinas, thus perceiving light quite differently from us (Prescott *et al.*, 2003). Recommended minimum levels of light intensity are 10-20 lux at bird's eye level. Insufficient levels of light cause abnormal development of the eye. Reducing light levels makes birds easier to catch for depopulation, and lower intensities are often used to reduce **cannibalism** and **feather pecking**.

It is particularly important to remember that housing restricts the ability of the hen to choose her own environment, and thus humans must assume responsibility for providing an environment that satisfies the **health** and **welfare** needs of the birds. There is increasing realization that poultry are sentient beings and, as such, require more than the basics for survival, as expressed in the **five freedoms**. More consumers in the 'developed' world now demand 'welfare-friendly' produce from less intensive housing systems.

None of the current housing and husbandry systems for commercial egg production is ideal in terms of hen welfare. Each has both advantages and disadvantages in terms of health and behavioural needs, which are equally important considerations for animal welfare. Abnormal pathology and behaviour are reported from all systems. Whereas housing and husbandry systems traditionally evolved to be practical, economic and productive, a comparatively recent change of emphasis has emerged. Applied ethologists have used economic models to determine how animals prioritize different behaviours and features of their environment (Dawkins, 1990; Weeks and Nicol, 2006) (**see: Economics of behaviour**). This fundamentally different approach to design aims first to make provision for the most important facilities and resources from the animal's point of view, and then to develop practical and economic housing systems to incorporate these. Aviaries and modified cages have been developed this way, and their designs are still evolving.

Battery cages

The vast majority (about 75% worldwide) of laying hens kept for commercial egg production are housed in battery cage systems, where 'battery' refers to an array of cages. These are commonly three to nine tiers high and completely made from wire, including a sloping floor (up to 8% is recommended),

P.382

which allows droppings to fall through and eggs to roll out on to collection conveyor belts. The number of hens kept in battery cages may reduce, as Switzerland outlawed them in 1992, Sweden in 1999 and the EC is also proposing to do so from 2012.

Conventional battery cages have been criticized for inadequate hen welfare by many sources, particularly in terms of the extremely restricted space allowance and associated disuse osteoporosis, plus the lack of facilities such as nestboxes, dust baths and perches causing **frustration** and preventing the expression of normal behaviour. Wire floors may be uncomfortable and lead to foot problems, although EU law now

requires that claw shorteners should be provided to prevent overgrowth. Claw shorteners are generally strips of abrasive material fitted on the inside of the front of the cage, near the feed trough that is usually fitted just outside the front of the cage. While hens feed they tend to attempt to scratch as they would if foraging, and thus file their own claws. Abrasion of the feathers against the cage sides is common.

To save costs, cage sizes have decreased and number of hens per cage increased to the point where it is usual for hens not to be able even to stand fully upright in a cage, and for the floor allowance to be so restricted that not all birds can sit down at any one time. Typical inadequate allowances are around 340 cm² per hen, the most common allowance in the USA for example, although restaurant chains and retailers may specify more generous allocations. In the EU, a space allowance of 450 cm² was taken to be insufficient and has been increased to 550 cm², which will increase when the specifications for modified cages come in (see below). It is difficult and time-consuming to inspect individual cages in high tiers. Walkways are not a legal requirement in most countries but these, plus uniform lighting at all levels, should be provided to aid inspection and removal of sick and dead birds.

The battery cage system is, however, not only the easiest to manage and automate, but also provides the cheapest eggs. Hygiene is usually superior because the birds have minimal contact with their droppings, and the lack of litter reduces dust and **parasites** considerably. There is a reduced risk of humans contracting disease from the hens or their eggs. Birds in battery cages are, on average, the most productive and healthy with relatively low levels of mortality. The preference of hens for small group size is satisfied, but not their preference for a large space. Feather pecking and cannibalism are rare in battery cages, partly because of small group size and the very restricted space allowance.

Modified cages

Various designs of modified (or furnished, or enriched) cages have been developed with the aim of meeting more of the hens' behavioural needs while retaining the health benefits and economic advantages of conventional battery cages. The effect of cage design on health and performance was considered by Tauson (1998). Priorities for hen welfare appear to be relatively small group size, more space, provision of nestboxes and perches and a substrate for foraging and **dust bathing**. Elevating the feed trough improves feather cover by discouraging activities such as stepping off perches on to the backs of cage mates, which causes feather damage.

Modified cages that are being used commercially include: (i) the Victorsson model for eight birds, with perches and litter box on top of a nestbox based on the Edinburgh modified cage design; and (ii) the Big Dutchman reversed furnished cage for ten hens, with curtained nesting area and litter provided on a belt (based on a design by Tauson). Cages that will accommodate large groups (20-60) are also being examined. These are essentially small aviaries, the definition of which relates to whether a human caretaker has to enter the enclosure to check the birds (aviary) or not (cage).

Providing perches costs little, but advantages include normal roosting and perching behaviour, reduced foot problems and increased **bone strength**. Perches can be provided in conventional cages, but the space restriction is not ideal and can slightly increase the number of cracked and dirty eggs and make it more difficult for hens to move around the cage. There can be strain differences in these parameters and in perch use.

Further research is needed to ascertain whether sham dust bathing is reasonably satisfactory for the birds. Artificial turf may be acceptable to birds in place of a litter substrate that has so many practical problems associated with it. Both the Victorsson and Big Dutchman furnished cages provide 0.06 m² (600 cm²) of floor area per bird. The EC has specified 0.55 m² as a minimum for all cages installed after 2003

(or 750 cm² per bird, including the nestbox and litter area). It is proposed that in 2012 this will apply to all cages. In addition, the proposed 'enriched' cages must be 45 cm high over most of the cage, and have a nest, 15 cm of perch space per hen, 'litter such that pecking and scratching are possible' and a clawshortening device. There is no explicit provision for a dust bath. In the rest of the world, cage design and stocking density may change to meet the welfare specifications of the large retail customers.

Aviaries

There are several variants of aviaries. Single-tier systems are increasingly common in the UK. These have a one-tiered wire floor containing feeders and drinkers and banks of nestboxes in the centre or at the side, a litter area and a stocking density of about 9 birds/m². The tiered wire floor system was invented in the Netherlands to make similar use of the vertical space in a house to battery cages. It resembles battery cages, but with partitions removed. Hens may move freely between rows of narrow tiers, three high, with feed and water provided on each level (see Fig. L.1).

Other commercial aviary systems include Boleg, Laco-Voletage, Natura and Marielund, all floor-based systems that provide tiers with slatted or wire floors to make more use of vertical space, with litter for scratching and dust bathing at ground level. There may be ladders for hens to use to move between tiers. Often the top tier is reserved for roosting perches. Drinkers tend to be placed over slats. Feed is usually distributed to each tier via flat-chain trough feeders. Tiers of nestboxes with egg-collection belts are placed throughout the house. Manure belts need to be provided to prevent hens from defecating on each other. Most commercial stocking densities are around 17-20 birds/m².

Aviaries are complex systems that place ergonomic demands on both birds and humans, particularly at depopulation. Outbreaks of severe feather pecking and cannibalism can occur

P.383

in aviaries, with mortality as high as 27%. Effects of stocking density on feather pecking are complex. Different strains vary in propensity to feather peck and plumage condition as well as in mortality and performance. Reported proportions of floor eggs vary between 2.5 and 11.5%. None the less, with experience and good management, layer performance can be similar to that in battery cages, and equally good production has been recorded for the 65% of laying hens in Switzerland that are kept in aviaries. Aggression is generally low in large flock systems. Rearing pullets in an aviary-type environment and providing a covered outdoor area seem to be important for success.

Fig. L.1. It is common in housing systems for groups of layers to find a raised, perforated floor to collect droppings beneath roosting perches, feeders and drinkers.

Percheries

Percheries use the vertical space in a house by having several rows and tiers of perches arranged on frames (see Fig. L.2). There is some overlap in terminology and design with aviaries. At each level, hens can access feed and water and may also move up and down or fly across to another set of perches or to a tier of nestboxes.

Hens are particularly likely to sustain bone breaks in this alternative system (although recent work suggests that birds may be getting more susceptible to fractures in all systems). They need to have access to perches and learn to fly during rearing. The spacing between stacks of perches and nestboxes is also very important. Design and management should also keep perches and birds' feet clean, otherwise problems such as bumblefoot may result. Fewer problems are encountered where litter is provided on the floor, but EC rules do not specify it, and also permit up to 25 birds/m², with a minimum of 150 mm of perch space per bird. Cannibalism and other problems are often associated with such high stocking densities. Percheries are less commonly found now for various reasons, not least the unpleasant working environment for humans.

Housing for free-range hens

Hens must have daytime access to pasture in order to be described as free range. Stocking density can be as high as 1000 hens/ha if there is good vegetation cover on the ground, but lower densities are

recommended to avoid health problems. Most producers restrict ranging within an enclosure (electric) fenced against predators and encourage birds to lay in nestboxes within the house. All houses provide perches for night-time roosting. Most houses also contain the drinkers and feeders to reduce losses to, and contamination by, wild birds as well to minimize problems with rain and freezing (see Fig. L.3).

Fig. L.2. Tiers of nestboxes in the 'Natura' perchery system. Note the perches in front that hens can fly on to, giving easy access.

Some provision of water outside is recommended. Houses may be fixed or movable. Fixed houses should be similar to deep litter or perchery houses to meet EC regulations. Movable housing can vary from small, wooden arcs or houses with wheels that are moved frequently to semi-permanent, large houses that tend to be moved for each new flock. Typical house stocking density is 10 hens/m².

Coccidiosis is a universal disease challenge in free-range flocks. Vaccination, good hygiene - including pasture rotation and frequent manure removal - and reduced stocking density all help to control coccidiosis. Because the birds are more active and, in most climates, exposed to cooler temperatures, they eat more. Thus, especially in developed countries, it is the most expensive system. Eggs must be sold for a premium for the system to be viable. However, in rural undeveloped countries, backyard flocks provide high-quality nutrition for humans at negligible cost.

There are some welfare problems associated with the free-range system, particularly in larger flocks. Both the health and the behavioural needs of the hens can be compromised by problems of bullying around pop-holes, feather pecking and cannibalism. Debeaking (**beak trimming**) is a widespread preventive measure that, in itself, is a welfare issue and is also practised to some extent in all other housing systems. Research is ongoing to find ways of encouraging hens to make full use of the range area

provided. Greater use of range is made by both individuals and a larger proportion of the flock when tall vegetation and trees are provided for cover. Providing wide pop-holes tends to encourage use of range, although in some

P.384

climates this can cause wet litter and hence problems such as ammonia and foot lesions.

Fig. L.3. Free-range layer house.

Minority systems

These include straw yards (barns) where birds are housed on deep litter with nestboxes and perches, similar to free-range housing. Slatted or wire floor systems are similar, but with perforated flooring that reduces contact between birds and their faeces. Welfare tends to be worse because possible health benefits are traded against loss of a medium in which to forage and dust bathe. Additionally, behavioural problems such as floor egg laying, feather pecking and cannibalism are common, thus adversely affecting the economics.

Learned helplessness

Learned helplessness describes the apparent failure to respond to a change in a situation after experiencing a lack of control in a similar, previous situation. The phenomenon was described originally by Seligman (1975), following an experiment in which dogs that had experienced random, electric shocks (from which they could not escape) failed to learn how to avoid being shocked by jumping barriers into another compartment within their experimental environment. It appears that the individual might learn that the unpleasant event occurs independently of their behaviour and generalizes this learning. Learned helplessness may explain apparent **apathy** in individuals in situations over which they perceive that they have no control as a consequence of their previous experiences.

Legislation to protect animals

Legislation to protect animals first developed in Europe and North America during the 19th century. The world's first law to protect animals was passed in the British parliament in 1822. It said 'that if any person or persons having the charge, care or custody of any horse, cow, ox, heifer, steer, sheep or other cattle, the property of any other person or persons, shall wantonly beat, abuse or ill-treat any such animal, such individuals shall be brought before a Justice of the Peace or other magistrate'.

There are three striking restrictions in this law:

1. Only some animals are covered. Many (e.g. **dogs, cats, pigs** and poultry) are not mentioned at all and, among the species that are covered, some, like bulls, are not indicated explicitly. One reason for this is that, at the time, there was a custom of arranging fights between animals. **Bull baiting** and other blood sports were popular, and the politicians were reluctant to make unpopular laws.
2. The law applies only to people who do not own the relevant animals. The Bill's advocates seem to have assumed that animal owners would want to protect and make good use of their property. Bad animal treatment is regarded as irrational or pointless - the kind of thing that would only be done by someone who does not share the owner's interest in protecting the value the animal represents.
3. Only what is described as *wanton* cruelty is covered. The adjective 'wanton' means undisciplined, random or motiveless, so those who passed this Bill do not seem to have been aiming to regulate established uses of animals.

There is clearly a link between 2 and 3: the need to protect animals by law arose from concerns about pointless cruelties perpetrated by third parties. This equation underpinned most legislation designed to protect animals until at least the 1950s. It was only after this that attention turned in a serious way to legislation intended to protect animals used, by their owners, in a *purposeful* way in intensive animal production, laboratories and elsewhere.

In intensive farm animal production of the kind practised today, conflicts between productivity and the interests of the animals are familiar (**see: Intensification of animal production**).

P.385

Modern farm animals are typically allowed less space than they once had, and many live in barren environments in which they cannot exercise their normal range of behaviours. Some kinds of genetic selection and **breeding** goals are associated with production-related diseases. These problems have given rise, particularly in Europe, to a new kind of animal welfare legislation. Broadly speaking, the point of this legislation is to prevent farmers from doing what, in fact, it is most profitable to do. For example, in intensive egg production it is economically sound to keep hens in small cages with very high stocking densities. In places without animal welfare regulation it is not uncommon for hens to be housed with as little as 300 cm² per animal. If there is no regulation or other mechanism in place, egg producers will be incentivized by market forces to keep their hens in very small cages. The alternative is to produce at a higher cost than their competitors, and this would not be feasible in the long term.

Recent growth in international markets has ensured that national legislation is both less effective in securing its welfarist purpose and harder to justify to domestic producers. Both consequences flow more or less automatically from the introduction of competition from producers in countries with less stringent laws. In response to this kind of problem there has been a drive in EU countries, as well as in countries that are members of the Council of Europe, towards harmonized European legislation. New rules on animal production designed to create a 'level playing field' (so far as legislation is concerned) are now regularly introduced. Since animal products are increasingly imported to the EU from countries beyond the reach of European jurisdiction, there is a limit to how far this kind of policy can succeed - unless, of course, it can be translated to the global level. Some global initiatives are on the way, but they remain at a very early stage.

It can be seen, then, that the rationale of animal protection legislation has changed dramatically over time. Recent legislation aims to protect or improve animal welfare that is threatened by market forces and intensive production. Earlier 'anti-cruelty' legislation, by contrast, was designed to protect livestock against irrational forms of misuse.

Today, the need for animal protection legislation goes beyond farm animal production, as is readily apparent when we consider the use of animals as tools in biomedical research. The benefits of this kind of animal use are clear, even if the question of whether those benefits could be obtained without using animals is contested; and biomedical animal research is certainly approved by a large percentage of the population. But many people worry about animals having to suffer for our sake. Such people want reassurance that there is a good case for doing the research: that its goals are definitely worth pursuing, and that those goals oblige the researcher to use animals. To address this kind of attitude, legislation has been put in place in many countries to protect **laboratory animals** from unnecessary **suffering**. The legislation is designed to ensure that live animals are used for experiments only when no other suitable method is available, that no more animals are used than is necessary and that, when they are used, animals are not caused more **stress** or suffering than is required by the experimental aims (**see: Three Rs principle**).

Lek

A lek is a relatively small area where males congregate and exhibit competitive displays to females. The lek does not contain resources of importance to females. Typically, 10-20% of males at a given lek secure more than half of the matings. Why males aggregate in a lek is hotly debated, although it is generally accepted that males form leks because they are unable to monopolize either females directly (female defence polygyny) or resources required for females (resource defence polygyny). Two key hypotheses are the 'hotspot' and the 'hotshot' hypotheses. According to the hotspot hypothesis, males gather at areas that have a high female encounter rate (several female territories may overlap in a particular area and/or females may travel along certain routes). In contrast, the hotshot hypothesis proposes that females are attracted to highly attractive males, and the less attractive subordinate males cluster around these successful males.

Lever pressing

An **operant response** (a response controlled by its consequences (**see: Conditioning - types of**)), commonly used in behavioural studies of learning. Lever pressing in this context typically results in the delivery of a food pellet to a hungry **rodent** and so allows clear quantification of the effects of other variables on the behaviour.

(SuH)

Libido

Libido can be defined as the manifestation of the sexual motivation in both males and females. In applied animal behaviour, the term is most often used to describe the willingness and eagerness of male animals (especially farm animals such as boars, bulls, stallions and rams) to mount and attempt to mate with the females. A number of factors have been shown to affect libido, including: genetics, hormonal factors, post-weaning management, nutrition and season.

Libido has a genetic component, with differences within and between breeds. In boars, crossbred boars have greater libido than purebred boars and, within purebreds, it has been shown that Duroc boars have lower libido than Yorkshire boars. With cattle, *Bos indicus* bulls have generally reduced libido relative to *Bos taurus* bulls and, within *B. taurus*, beef breeds have lower libido than dairy breeds. In horses it has been reported that Arab stallions have greater libido than Quarterhorse stallions.

The major hormonal influence on libido is exerted by **androgens**, especially **testosterone**. Low-libido animals

P.386

generally have lower circulating testosterone levels than their high- or normal-libido **conspecifics**. The whole picture, however, is not this simple, and other hormones such as **oestrogen**, **luteinizing hormone (LH)**, **prostaglandins** and **thyroid hormones** have also been implicated in the hormonal control of libido.

Sexual inhibition can occur in management systems that keep young, post-pubertal males in male-only groups, and this has been reported in bulls, boars and rams. Ideally, males should have some contact with females during rearing but, at sexual maturity, they should be allowed only supervised contact with females to prevent any **aggression** from them that may suppress libido in the future.

There is some evidence to suggest that libido is diminished by rapid weight gain during the post-pubertal period. For ruminants, high levels of concentrate diet and high feeding levels appear to reduce libido relative to forage-fed animals. However, protein levels need to be maintained. Boars on low-energy and low-protein diets show low libido.

Many animals appear to show reduced libido in relation to climatic extremes, with libido particularly reduced in extreme heat. Some **sheep** breeds and *B. indicus* bulls are reported to have reduced libido in cold weather.

(JNM-F)

Light and behaviour

Light is essential for many animals' lives and can have profound influences on their behaviour and **welfare**. These are discussed below with respect to the frequency, intensity, timing and duration of light.

Frequency of light

The frequency (or wavelength) of light reflected or emitted by objects is the characteristic that humans perceive as colour. There is a wide range of sensitivities to light frequencies within the animal kingdom, and animals are often categorized according to the number of types of retinal cone (colour-sensitive) cells they possess, i.e. monochromatic (e.g. marine mammals), dichromatic (e.g. most terrestrial mammals, including **dogs, horses, pigs, goats, cattle, sheep, deer** and many primates), trichromatic (e.g. humans and other primates and several marsupials) or tetrachromatic (e.g. some arachnids, insects, **amphibians, reptiles**, fish and birds). Some animals have five (flies and some butterflies) or even 12 (stomatopods - 'mantis shrimps') types of receptor for colour vision (see also: **Visual perception**).

Colour vision is usually dependent on differing signals from different cone types, and therefore it is believed that most dichromats have only limited colour perception. It has been argued that, despite having only one type of cone cell, monochromatic marine mammals do perceive colour, registered as a balance between signals from the rods and cones. Even within individuals, colour sensitivity can differ. For most animals, as the intensity of light decreases, the cone cells become non-functional and vision becomes more reliant on the rods, which are insensitive to colour, sometimes called scotovision. Some nocturnal geckos and moths are able to use colour vision in dim moonlight situations when humans and most other animals are colour-blind. Colour perception mechanisms are highly dependent on evolutionary factors, of which the most prominent is thought to be recognition of food sources, but it is also used in many other aspects of behaviour such as **mate choice, crypsis** and navigation.

Some animals (e.g. many insects, birds, lizards, frogs, turtles, fish and some mammals) are visually sensitive to frequencies higher than are most humans, and can see ultraviolet (UV) light (this is prevented in most adult humans, as the cornea and lens block ultraviolet frequencies). The functions of UV vision are not yet well understood, but possibilities include urine-mark visibility in degus, voles and mice, social communication in degus and birds (including domestic poultry) and twilight UV vision in **rats**. Beyond the lower end of frequencies visually perceived by humans, some pit-vipers are sensitive to infrared wavelengths and therefore 'see' heat emitted from potential prey.

In the sky and underwater, scattering of incoming light produces partial polarization that varies with the position of the sun and the direction of view. Some animals (e.g. insects, cephalopods, birds and fish) possess the ability to see polarized light, and may use this in a similar way to colour vision, e.g. signalling, species recognition, mate choice, orientation and navigation. Cuttlefishes and other cephalopods have only one spectral photoreceptor class and are therefore probably incapable of colour vision; however, some possess the ability to change colour rapidly in what appears to be signalling behaviour; the replacement of colour with polarization vision seems a plausible suggestion for how this might occur.

Many animals are housed under artificial light sources, the most common being incandescent and fluorescent lamps. These are designed primarily for the human visual sensory system, and as a consequence have characteristics that can influence animal behaviour and, potentially, welfare. Both incandescent and fluorescent lamps emit little or no UV wavelengths. As discussed above, UV vision is used widely by some species; however, UV-deficient environments do not appear to be **aversive** and there appear to be few, if any, consequences for welfare. Some artificial lamps are designed to emit UV frequencies, and these have been shown to be beneficial in environmental **enrichment** for **turkeys** (Lewis *et al.*, 2000) and breeding in reptiles. Furthermore, commonly available fluorescent lights flicker on and off at a frequency so great that most humans perceive this as a constant light, because it is above our

critical flicker fusion frequency (CFFF). However, other animals have a higher CFFF and therefore perceive these lights as flashing on and off.

Despite this, studies on light preferences have shown that animals (primarily birds) do not find this aversive, although it could explain why, in vision studies, some species appear to be unable to recognize images on standard computer monitors and other screens that also have refresh rates below the species' CFFF (Railton *et al.*, 2009). Most animals are insensitive to infrared light and it is therefore often recommended that, if their behaviour during the dark phase is to be recorded, infrared lights and suitable recording equipment can be used to avoid disturbing them.

Intensity of light

Light intensity can have demonstrable effects on behaviour; for example, low intensities reduce **preening** and foraging, but increase sleeping in broiler **chickens** (Alvino *et al.*, 2009). The

P.387

intensity of light from a point source decreases as the inverse square of the distance from the light source. This means that light intensity decreases rapidly as the viewer moves away from the source. In many animal housing scenarios, if light intensities for animals in tiers or blocks are maintained by measuring intensity at the top levels, the intensity is likely to be too low for animals on lower levels or, if intensity is maintained for those on the bottom levels, the intensity will be too high for animals on the top. Animals close to the lights (e.g. animals on the top levels of banks of cages) may need some protection from these intensities. It should also be remembered that albino strains of animals often prevalent in laboratories are more susceptible to light-induced blindness than are pigmented strains.

Low light intensities are sometimes used to calm animals, for example when pigs are being mixed or when broiler chickens are being caught for taking to the abattoir. Similarly, poultry are often housed at low light intensities (e.g. <10 lux) to reduce injurious **feather pecking**. However, these intensities (especially in combination with elongated photoperiods) can lead to bupthemia (an elongation of the eye), retinal degeneration and even retinal detachment. Preference studies have indicated that turkeys prefer greater light intensities than are usually provided commercially (Sherwin, 1998). In some laying hen systems, light intensity is gradually decreased at the end of the light phase to give the hens the opportunity to move to the perches while there is still light and thereby avoid risking injury. Different intensities of light are preferred for some behaviours (e.g. Sherwin, 1998; Taylor *et al.*, 2006), indicating that provision of different intensities within an enclosure could be a suitable form of practicable and inexpensive environmental enrichment for captive animals.

Timing of the light phase

If there are no external influences, many behavioural, biochemical and physiological processes will follow an endogenously generated cycle of approximately 24 h (nycthemeral or **circadian rhythms**). These rhythms can sometimes be entrained by external cues (Zeitgebers), a primary one being light. The timing of the light phase is therefore fundamental to animals, as it influences behaviours such as **sleep**, social interaction, **elimination**, learning ability and regular feeding patterns. The primary circadian 'clock' in mammals is located in the suprachiasmatic nucleus in the **hypothalamus**. This receives information about illumination through specialized ganglion cells in the retina, and communicates it to the pineal gland. In response, the pineal secretes the hormone melatonin, which peaks at night and ebbs during the day. Patterns of animal activity are often expressed according to light and dark patterns, e.g. **nocturnal** (mice, rats, **hamsters**), **diurnal** (most avian species, farm, **zoo** and **companion animals**) or **crepuscular** (owls), i.e. active at dawn and dusk. Some animals are extremely flexible and adapt their activity patterns to the activity of humans (**guinea pigs**).

Many laboratory animals are nocturnal, and there is growing acceptance that gathering data from animals during times when they would normally be asleep (i.e. during our human light phase) is not best practice for scientific validity or animal welfare. In studies of nocturnal animals in the dark, red lights are often used to allow humans to observe the animals while avoiding disturbance and gaining more representative data. Such considerations should be extended to the chronobiology of other species. In studies requiring animals to respond normally in the dark, infrared lamps and suitable recording equipment can be used.

Duration of the light phase

In nature, changes in the duration of the light phase can predict seasonal periods of weather conditions, food availability, predator activity, etc. This in turn can affect the seasonal timing of behaviours such as migration, hibernation and **reproduction**. Most laboratory and intensively reared farm animals are totally under the influence of their caregivers with respect to the duration of light exposure, and sometimes this is manipulated to mimic seasonal effects, e.g. layer hens are placed on a regime of increasing daylength to induce egg laying.

Many different patterns of intermittent artificial light have been extensively researched, mainly in efforts to increase poultry production (e.g. Lewis *et al.*, 1996). It has been shown that a simple pulse of light can be used to indicate 'dawn'. If this flash occurs 1 h before an 8 h period of light, it may have the same stimulating effect as a 9 h period of continuous light. The effects of different **photoperiods** have also been extensively researched, again mainly in relation to poultry production. In some countries, some farmed species are housed under almost continuous light, as this keeps the animals active and eating, thereby achieving **slaughter** weight at an earlier age. However, longer photoperiods have been associated with increased mortality in broiler chickens (Lewis *et al.*, 1996). It is widely believed that interruptions to the dark phase are aversive or perhaps even stressful to animals; some codes of recommendations indicate that animals should be provided with an uninterrupted period of darkness.

Light/dark test

The light/dark test is used to measure anxiolytic-like or anxiogenic-like activity, especially in mice, as an animal model of **anxiety**. This test is based on the fact that **rodents** display spontaneous **exploratory behaviour** in response to mild

P.388

stressors (e.g. novel environment and light) and show an innate aversion to brightly illuminated areas. The test apparatus consists of a small, dark, safe compartment and a large, illuminated, **aversive** compartment. Transitions between light and dark compartments and exploratory behaviours are part of the scoring of behaviour. Anxiolytic drugs have been found to increase **locomotion** and time spent in the light zone, whereas anxiogenics decrease them.

Loading animals for transport

Livestock are transported from rearing units to farms, between farms, to and from livestock auction markets and to **slaughter**. Loading of animals on to transport vehicles can cause a significant amount of the overall **stress** associated with **transport**, as evidenced by increases in **heart rate** and the blood levels of stress hormones. The animals may need to be caught, restrained and confined in small spaces, encouraged to move using coercion and may be subjected to the physical exertion caused by, for example, movement, running and climbing loading ramps. Forcing animals to move quickly may cause them to slip and fall, or bump into pen and raceway walls, causing bruises.

Animals such as **horses**, **cattle**, **pigs** and **sheep** are loaded as groups or individuals, while small animals such as poultry and **rabbits** are initially collected into transport crates, which are then loaded on to the transport vehicles using a fork-lift truck. With broiler **chickens**, which are often reared intensively in sheds of 30,000 or more birds, and spent (culled) hens, catching (depopulation) involves hard, physical labour under often unpleasant working conditions. This, together with the low economic value of each bird, may result in reduced care when handling and, thus, compromised **welfare**. Mechanical catching of broilers is used in some countries in an attempt to overcome these problems, but with varied success. Particularly with intensively reared species like pigs and poultry, which have a relatively small amount of contact with humans, loading may be the first time that animals come into close contact with people and experience the **fear** associated with this.

In poultry, catching birds can cause trauma, particularly bruising and haemorrhages, and dislocated or broken bones. Birds caught and carried by a single leg are more susceptible than those caught by both legs. The reported prevalence of bruising ranges widely, and may be up to 20%. A vehicle carrying 6000 broilers may take 1 h to load. The transport crates restrict ventilation and, in hot weather, this can lead to heat stress for the birds until the movement of the vehicle promotes air circulation. So-called day-old

chicks are handled at high speed in largely automated systems in modern hatcheries. These move the chicks using rubber belts that operate at progressively increasing speeds, with deflector plates to sort the chicks, before packing them into specially designed cardboard transport boxes that accommodate about 100 chicks. There is considerable scope for stress and damage to the chicks because of the speed of operation.

Large animals are usually walked on to the vehicle. This may involve the use of loading ramps. In many vehicles these are too steep ($>20^\circ$ to the horizontal), particularly the internal ramps giving access to the upper decks, making it very difficult for animals to climb and descend them. In modern vehicles ramps are often partly avoided by the use of raised loading decks, or replaced by hydraulic lift systems, which considerably reduce stress and the danger of injuries to the animals. In all loading systems, raceways and passages should: (i) be appropriate in width; (ii) not have sharp bends; (iii) not have protruding fixtures on which animals could damage themselves; (iv) not have distractions that might cause animals to baulk; and (v) have floors that are non-slip and freedraining. All systems must be secure and proofed against escape of animals.

The point of loading is important in that the decision must be taken as to whether the animal is legally fit to travel. In Europe, animals that are ill, infirm or fatigued (unless only slightly affected and where the intended journey is unlikely to cause them unnecessary suffering) are unfit to travel (EU Council Regulation (EC) No 1/2005). Each animal must therefore be able to be loaded without force and be able to bear weight on all four legs.

(PDW)

Local enhancement

The term 'local enhancement' was first introduced into the **social learning** literature by Thorpe (1956/1963). Social learning refers to a group of mechanisms in which the observation of other individuals, or the products of their activities, facilitates or enables the acquisition of novel behaviour. However, as with most social learning terminology, there has been considerable confusion and disagreement with regard to the precise meaning of local enhancement.

Thorpe's (1956/1963) first priority was to distinguish local enhancement from **imitation**. He considered imitation a cognitively complex ability. He defined imitation in terms of 'copying a novel or otherwise improbable act or utterance, or some act for which there is clearly no instinctive tendency'. Hence, when one imitates one learns to perform a novel behaviour directly from watching a demonstrator.

Thorpe argued that there are several different processes that can, on the surface, resemble true imitation, but that these are, in fact, much more cognitively simple. He identified local enhancement as one of these more simple processes. He defined it as 'an apparent imitation resulting from directing the animal's attention to a particular object or a particular part of the environment'. Once the animal's attention has been brought to a particular object or location by the actions of a demonstrator, it might be more likely to engage in individual exploration and, due to being exposed to similar physical and environmental variables, may end up producing matching behaviour. However, unlike with imitation, the animal has not learned the matching behaviour directly from watching the model; instead, the behavioural match is a by-product of individual learning shaped by exposure to similar physical constraints.

Since Thorpe was primarily concerned with defining local enhancement in contrast to imitation, he emphasized the circumstances in which it might lead to organisms producing topographically matching behaviours. Although it might sometimes lead to animals producing physically similar behaviours, this need not necessarily be the case. An animal

P.389

could have its attention drawn to a particular object or part of the environment and then use quite different behaviours from the demonstrator when it comes to interact with it. For example, a flock of parrots might come across a site where elephants have been excavating for minerals in a mudbank. If, as a direct result of exploring these excavations, the parrots discover the nutritional benefits of the minerals, this would constitute local enhancement. Even if the parrots never directly observed the elephants at the site, or if they used a vastly different behavioural technique, the mediating process would still qualify as local enhancement. All that is required for local enhancement is that an animal has its attention drawn to a particular object or part of the environment in a way that would not have occurred without exposure to the demonstrator or its products, e.g. scent cues or excavations (Heyes, 1994).

Local enhancement is very closely related to Spence's (1937) concept of stimulus enhancement. Spence defined stimulus enhancement in terms of a demonstrator's behaviour increasing the probability that an observer will be exposed to and respond more vigorously towards a certain class of **stimulus**. Thorpe had defined local enhancement in terms of an observer paying attention to the particular object or part of the environment to which the demonstrator had been oriented. Spence's concept of stimulus enhancement extends the effect of the demonstrator so that an observer generalizes its activity to all objects of the same physical appearance.

Heyes *et al.* (2000) point out that, as Thorpe defines it, although local enhancement may be the product of learning, and it may give rise to learning, it does not constitute a learning phenomenon in itself. Naturally, it follows that if it does not qualify as a learning phenomenon, it can not be considered a type of social learning. As they put it:

For example, a rat may be attracted to odors deposited at a food site by a conspecific (Galef and Beck, 1985) because these odors have been associated with reward, and as a result of consuming the food the rat may acquire a flavor preference. However, the rat's approach to the food site, the phenomenon of local enhancement itself, is a response to current stimulation, and not necessarily either a precursor or a product of learning.

(Heyes *et al.*, 2000)

Upon identifying the limitations of Thorpe's concept, some researchers have suggested discarding the category of local enhancement altogether. However, there are circumstances in which the concept of local enhancement is important, especially if one wishes to establish whether social learning has occurred or not. For example, Heyes and Dawson (1990) found that rats would compensate for a 180° difference in perspective from a demonstrator and push a vertical bar in the same direction as shown (i.e. left to right or vice versa). Although originally the rats' behaviour was interpreted as imitation, it was later shown that the results were likely to be due to the subjects responding to scent cues deposited by the demonstrator on the bar. If the rats had, in fact, pushed the bar in the direction demonstrated in the absence of scent cues, this would constitute social learning. As the results stand, local enhancement remains a likely explanation.

Many researchers have tended to use 'stimulus enhancement' and 'local enhancement' as if they were synonymous, distinguishing them only in terms of whether an observer has its attention drawn to an object (referred to as stimulus enhancement) or to a part of the environment (referred to as local enhancement). However, if one maintains the subtle differences inherent in Spence's and Thorpe's original definitions, one can establish with greater certainty whether social learning has actually occurred.

Locomotion

Locomotion refers to voluntary movements that displace the whole body. This is usually confined to walking, trotting and galloping/running, but many species jump, swim and canter. Other limb movements such as kicking or pawing are performed but do not involve whole-body movement.

Locomotion in mammals is primarily by forward motion; sideways and backward motion can be performed, but muscles are designed for forward propulsion, and any other motion is much less efficient. During forward motion the centre of gravity is moved towards the front limb by the propulsive efforts of the hind limb, and the front limb is raised and repositioned to maintain the animal's balance. The positioning of the limbs may be in either a symmetrical or asymmetrical pattern, and quadrupeds may be supported by three, two, one or no limbs at any particular time. The faster the **gait**, the fewer the supporting limbs. The head may be held high to place the centre of gravity as far back as possible. Animals change their gait according to their velocity requirements. There is a velocity above which it is energetically more efficient to trot than to walk, and another where galloping is preferable to trotting.

The walk

Walking is a gait where each foot is on the ground for at least 50% of the stride. Each limb is lifted by shortening the leg through flexion of the joints, using especially the hip, knee, hock and digital flexor muscles. The limb then enters the swing phase and is placed on the ground through slow extension of the joint. Once the limb is on the ground, it checks and supports the load by tensing all the extensor muscles, particularly in the digital, hock and stifle regions. The sole of the foot is then pushed hard against the ground by contracting the digital flexors, thus enabling the pushing phase to begin, followed by the hanging-limb and swing phases. The limb motion is therefore a cyclical, not an intermittent, process. The

quadruped walk can be considered as two people walking out of phase, one behind the other, so that four distinct sounds of the feet contacting the floor are heard. As the walking speed increases, efficiency decreases as the thrust phase (when the limb is supporting) is reduced at the expense of the hanging-limb phase. The major thrust is provided by the hind legs. The fore limbs, although typically supporting about 55-60% of the load of the animal, act mainly to position the limbs to enable them to act as support agents and steer the load.

During turning the limbs on the outside of the turning circle are abducted or rotated outwards, and those on the inside are adducted or rotated inwards, resulting in a change in direction. The main pivots for the fore and hind limbs are the shoulder and hip, respectively. All limb movements contain an accelerative and a decelerative force. During turning the outer limbs increase their accelerative force while the inner limbs increase their decelerative force.

Walking behaviour changes with the degree of confidence that animals have in being able to stay upright. For example, if the floor is slippery or the building is poorly lit, many species will shorten their stride and slow down the rate of walking.

The trot

The trot is used by many quadrupeds for long-distance motion that is more rapid than the walk. It is a symmetrical gait providing an even motion. For this reason it is used frequently by horses in regular motion and cows with full udders, the pendulous nature of which makes the cow reluctant to increase her speed to that of a gallop. When stimulated to move quickly over long periods, as for example if a herdsman hurries a cow down a track for **milking**, she will trot, as this provides a fast, even motion so that the forces on the udder can be absorbed in a rhythmical, swinging motion. In the trot, diagonally opposite limbs are used synchronously: left hind and right fore are followed by right hind and left fore. In a fast trot there is a period between limb changes when there are no limbs on the ground.

The gallop

The gallop is the fastest gait, and involves an asymmetrical step pattern and a lengthened, free-gliding phase. In small mammals this is accompanied by flexion of the back, but in large mammals this does not contribute to the propulsive force, which is provided mainly by the hind limbs. In the gallop there is a leading front limb, followed by the other front limb, then a pause after which the two hind limbs are placed on the ground, one fractionally before the other.

The canter

The canter is a gait of intermediate speed between a trot and gallop. It is a three-beat gait, leading on one hind limb, then the other hind limb together with the diagonal fore limb, and finally the other fore limb.

Motivation for locomotion

Animals are motivated to move in response to demand for food, water, companionship, shelter, safety, **grooming**, a sexual partner, more **space** and many other resources. This motivation increases with the duration and severity of resource restriction, especially of space. Many animals, particularly those that evolved as free-roaming animals that had to travel considerable distances in search of food, appear to need a certain amount of exercise to stay healthy and productive. Regular exercise in the form of supervised walking for tethered horses and cattle will increase muscle and bone growth in growing animals, prevent limb disorders - especially arthritis - and improve behaviour. Recommended allowances

are for about 1 h walking per day at about 3-4 km/h. As these animals typically walk for 2-4 km/day, it is likely that this constitutes a requirement. Range conditions may necessitate that cattle walk long distances to water every 2 or 3 days, sometimes up to 40 km, but this will reduce feed intake and milk production.

Effects of the environment on locomotion

The environmental features with the greatest effect on locomotion are the spatial structure and the type of accommodation, including lying and walking areas. These environmental effects interact with each other, and the animal's perception of the environment is modified by its experience. There is a pronounced **circadian rhythm** of activity in most animals.

In both housed and **free-range animals**, the available space is one of the main determinants of locomotory activity. In the **grazing** animal an increase in area and reduction in food availability forces it to walk further to search for food. For example, cattle on rangeland conditions have been recorded as walking three times as far as cattle on intensively managed pasture. Increases in locomotion can be caused by external **parasites** such as flies, which interrupt grazing activity. This encourages grazing animals to move about and search for open, windy areas where they can lose the attention of the parasites, which normally attack when they are stationary, especially lying down. This may lead some animals to move to altitude - or even out to sea - to avoid being bitten by flies.

An important consequence of excessive treading activity by hooved animals on poorly drained and clay soils is the loss of soil stability and eventual poaching damage. With housed cattle and horses the provision of adequate space for locomotion is a complex issue. Although a considerable proportion of locomotion is still associated with feeding, a significant amount is associated with social and other activities. This is because animals eating conserved food spend less time eating than grazing animals, they are stationary while they eat and the greater stocking density in a building than at pasture encourages more social interaction, especially grooming.

Space for locomotion is often restricted in animal **housing**. Caged animals most obviously suffer restriction of locomotion, but domestic animals in loose housing may also suffer restriction of movement. For example, in a cubicle house for dairy cows the space for walking is provided in the passageways between cubicles, in the feeding passage and occasionally in a separate exercise area. If the amount of space provided for locomotion is decreased below 4-5 m² per cow, it is likely that locomotory activity will initially increase for a few days because of **aggression** caused by competition for space. After this, however, locomotion decreases due to the restriction in space availability.

The floor (**see: Flooring**) is the most important part of the house in its influence on locomotion. Floor properties that influence locomotion include: (i) friction, which determines the slipperiness of the floor; (ii) hardness, which determines the

P.391

loading on the limb; and (iii) the surface profile, which determines the stress loading on the foot, as well as interacting with frictional properties of the floor. Friction can be measured as the force required to start the motion of an animal's foot across the floor (static friction) or that required to maintain this motion (sliding friction). There are both horizontal and vertical components to this force, and the ratio is known as the coefficient of friction. Although it has been found with cattle that the number of slip movements by the leg increases rapidly when the coefficient of static friction decreases below 0.40, in practice cattle probably show a consistent increase in floor preference as the coefficient of friction increases. If animals also lie on the floor, as in stalls, they may show more injuries to the legs as hairless patches, swellings and wounds, and fewer slipping injuries as the coefficient of friction increases.

For loose-housing systems where minimizing slip is the main concern, the minimum coefficient of friction depends on the surface profile. For solid floors it should be at least 0.40, for slatted floors 0.35 and for perforated floors 0.25. The frictional properties of a solid floor may be improved by cutting grooves in a squared pattern; for example, with cattle it seems the optimal size should be 4 cm sides to the squares. This disrupts the floor profile and gives the animal's foot a greater vertical area against which it can apply pressure during the pushing phase of each stride. The repeated passage of animals over a solid floor wears away the deformations in the floor profile created by initial tamping or grooving. In cattle, slips in excess of 500 mm are common on slurry-covered smooth concrete, especially during mounting behaviour. During the slip the hooves, especially in the front feet, turn outwards from the direction of travel.

A comparison of different floor surfaces shows that soil is the most slip resistant, that a covering of slurry increases slip by 56% and that tamping increases slip resistance more than grooving. On slippery floors animals modify their behaviour to reduce the incidence of slipping. They reduce their speed of walking and reduce the angles of extension of the limbs to the floor. Slip is most likely when the foot first touches or leaves the floor and the vertical loading is least. The further the foot is placed in front of or behind the centre of the stride, the less the vertical force and the greater the chance of slip. Hence stride length is reduced as the animal attempts to compensate for the floor conditions.

Slatted floors present an obstacle to normal locomotion in domestic farm animals, in particular cattle, but also in pigs and sheep. They cannot avoid the slots, but their claws often slip into them, causing contusion of the sole and exungulation. To avoid excessive pressure on the sole, slot width should be controlled and, to prevent faeces building up on the slats, slat width should be controlled. Slats cause animals to slip more often and they alter their locomotion posture, orienting their heads more towards the floor.

Younger animals, particularly those at **play**, are more likely to engage in the faster forms of locomotion, like gambolling and galloping, than mature animals, who spend less time in play and for whom it may be dangerous. The oestrous state also has a major influence on locomotion, often increasing it by a factor of 3-4 on the day of **oestrus**. Increased locomotion is also observed just before **parturition**, whereas it will often decrease after both oestrus and parturition.

Lameness is the clinical exhibition of an abnormality of the musculoskeletal system in one or more limbs. This abnormality can arise from many different things: congenital defect, infectious or metabolic diseases or trauma induced by environmental factors. During lameness, the supporting- or swinging-limb periods, or both, are shortened, so that the stride length is reduced. Reduction in the supporting limb period is most common with acutely painful lesions such as a sole abscess or chip fracture, as the pain is accentuated by pressure on the limb. Relief is also gained by relieving pressure on the diseased foot while standing. When the swinging-limb period is contracted, this is often associated with increased abduction (bringing the legs closer together) or adduction (the opposite movement), as the animals may attempt to decrease load bearing by a particular part of the foot. Some unevenness of gait is evident before and after each lameness incident. Systems for scoring animals for the severity of lameness based on the associated behavioural changes have been devised, but their reliability may be variable.

In conclusion, locomotion represents a major need in most animals, but particularly for domesticated animals kept in restrictive environments. Keeping animals on unsuitable floors or with inadequate space will lead to behaviour problems and limb disorders, in particular lameness. This represents a common cause of welfare problems in domesticated animals.

Logic

Logic is a key element in all scientific reasoning. By combining observations and assumptions it is possible, by means of it, to derive new insights. For example, some people have argued that dogs do not have **self-**

consciousness in the following way: if dogs are self-conscious, they will be able to recognize themselves in a mirror, but experiments show that dogs are not able to recognize themselves in a mirror, therefore dogs are not self-conscious. Such derived insights serve as hypotheses to be tested through further scientific enquiry.

In the philosophy of science it has been claimed that science proceeds by combining observations, previous hypotheses and background theories, and then pressing logic into service to derive new hypotheses that, in turn, are challenged by observations (from which, once again by means of logic, new hypotheses are derived). This is called the hypothetico-deductive method of science. The successful attempt to challenge a hypothesis by means of observations is called falsification.

Logic allows one to safely derive new insights from old ideas precisely because, in a way, the derived insights are *not* new, although they may be new in the sense that one has not thought of them before. However, they are old in the sense that they are already contained in the body of **knowledge** from which they are derived.

Take the example of the dogs mentioned above; this is a logically valid argument, which means that it is impossible, without contradicting oneself, to accept the premises and reject the conclusion. This is so because of the logical structure of the argument:

1. If p, then q.
2. Not q.
3. Therefore not p.

P.392

Whatever sentences one substitutes for 'p' and 'q', it remains certain that you cannot consistently accept 1 and 2 and reject 3. This is so in virtue of the way the concepts 'If ... then ...', 'not' and 'therefore' are defined. Notice that the fact that the argument is valid does not mean that the conclusion is true. One may, for example, doubt the conclusion of the argument about dogs because one doubts that the ability to recognize oneself in a mirror really is a criterion of self-consciousness.

The study of the various forms of valid logical inference is called formal logic.

(PS)

Longevity

Longevity refers to the length of the lifespan of an animal. Environmental, genetic and production factors play important roles in determining the longevity of an individual. Longevity between animals raised for meat and those raised for reproductive purposes have different factors that determine lifespan. Animals raised for meat have, on average, a significantly shorter lifespan than reproductive animals. Most meat animals are slaughtered at either the tail end of adolescence or the beginning of maturity, when meat quality is still desirable. This short lifespan decreases **culling** of these animals due to reasons such as **disease**, **lameness**, inefficient production and age. Short longevity is desirable for meatrearing animal producers because this gives producers maximal profit for minimal input (i.e. time and resources). To achieve this goal of a short life for meat animals, selection for both high **growth rates** of muscle deposition and larger body structure has been successful. Management practices play an important role in controlling environmental factors to encourage maximal growth rate and decrease disease.

Longevity goals for **breeding** animals are the opposite of those for meat-reared animals. Increased longevity will increase the number of productive years and most likely increase the number of offspring produced, therefore increasing profit. Many factors play a role in determining the longevity of these animals. Environmental factors such as **housing** type and management practices can cause either acute or

chronic **stress** that have an impact on longevity. In cases of acute stress, the animal may succumb to sudden death, usually from localized regions within the body - e.g. cardiovascular failure, respiratory disease, abscess rupture, GI tract torsion, etc.

In cases of chronic stress, the animal as a whole can suffer detrimental effects (decreased immune function, reproductive failure and decreased growth rate) that can give reason for the animal to be culled. Culling a reproductive animal depends on factors such as stage of **gestation** or **lactation** and severity of problem. Longevity and production rate of the parental lines play a role in determining the potential for their offspring. High offspring-yielding parents have a greater potential to have high offspring-yielding progeny, thus increasing the potential longevity of their offspring. If an animal becomes unable to reproduce or has low reproductive rates, it is typically culled from the herd, flock or group. Reproductive failure is the primary factor in determining breeding animal longevity. Reproductive failure can be due to genetic, environmental or management issues. Other reasons for decreased longevity or reasons for culling are age, lameness and disease.

(ELS)

Lordosis

Lordosis is the characteristic position that a female animal in oestrus adopts to signify a willingness to mate with a male counterpart. The female may lift her tail sideways and arch or stiffen her back, thereby exposing the perineum and allowing her to adopt a secure position before being mounted by the male.

The sex hormone **oestrogen** is required for lordosis to occur, and is released in greater levels during the periovulatory period.

(LW)

See also: Sexual behaviour

Lordosis quotient

The lordosis quotient is a measure of female sexual receptivity/motivation and is the proportion of mounts by a male in which the female shows a clear lordosis response. It can form part of a standard test in a laboratory setting; for example, a female rat may be presented with a male on ten occasions in order to calculate her lordosis quotient.

Lorenz, Konrad

Konrad Lorenz (1903-1989) was born on 7 November 1903 in Vienna, Austria, graduated in 1928 as a doctor of medicine from the University of Vienna and was awarded his second doctorate (PhD) in 1933. He was appointed to the Chair of Psychology at the University of Königsberg in 1939, but was drafted into the army medical service in 1941 and taken as a prisoner of war in 1942 by the Russian army. Following his

release in 1948 he worked at the University of Munster before moving to the Max Planck Institute for Behavioural Physiology, where he stayed until his retirement in 1973. A key feature of his work was his attempt to understand behaviour from both functional and causal (mechanistic) perspectives. Lorenz's best known popular works include *King Solomon's Ring* and *On Aggression*, which continue to inspire many into a career in biology. In 1973 Lorenz shared the Nobel Prize for physiology or medicine with **Niko Tinbergen** and **Karl von Frisch** for 'discoveries in individual and social behaviour patterns'.

Luteinizing hormone (LH)

Luteinizing hormone (also called lutropin) is a **gonadotropin** produced by the anterior **pituitary gland** in both males and females that stimulates the **gonads** of each sex. Its name is derived from the early identification of its role in the final maturation of the ovarian follicle, resulting in ovulation and the formation of the corpus luteum as a result. In the male it stimulates the Leydig cells to produce the androgen **testosterone**, which results in spermatogenesis. LH is therefore also known as interstitial cell-stimulating hormone (ICSH).

(DSM)

P.393

Lying

Lying allows animals to rest, hide and **sleep**, which are important for the recovery of body systems and **health** and for safety. It can also be used for maintaining associations with **conspecifics**. It is an important behaviour for which animals demonstrate a strong **motivation**. Indeed, some scientists have argued that maintaining adequate lying time is at least as important as maintaining adequate feeding time, because feeding can be accelerated by eating faster, whereas lying cannot (**see: Needs**). Animals that may be deprived of lying include those that are transported long distances over several days in crowded conditions (**see: Transport**) and those that are kept in conditions with unsuitable **floors** to lie on, such as concrete floors without any bedding. Some animals may physically have sufficient space to lie down but be afraid to if other animals are standing close to them in a moving vehicle. Indeed, if an animal lies down in a moving lorry, it may be unable to get up because other animals close over around it and occupy its space.

Lying deprivation can have negative effects on animal **welfare**, as demonstrated by behavioural and physiological measures. For example, when deprived of lying, cattle stamp their legs, regularly reposition themselves, shift their weight from side to side, swing their heads and occasionally butt each other, all of which appear to demonstrate **frustration**. They interact more with their **housing**, possibly redirecting their attention to alleviate the stress of deprivation. There is also physiological evidence of increased **stress** - increased **ACTH** (**adrenocorticotrophic hormone**) concentrations and a greater cortisol response to an ACTH challenge. **Growth hormone (GH)** concentrations may be reduced and the **immune system** adversely affected. Physically, animals may be subjected to foot disorders, such as sole haemorrhage in cattle (**see: Lameness**).

Both physical and physiological factors can compromise the amount of time available for lying. It is suspected that some high-producing animals - for example dairy cows - need extra rest, but also that they often do not have time for it because of the longer periods required for **feeding**, **rumination**, etc. Hence there is a negative relationship between lying time and milk yield in **grazing** or indoor dairy cows. There has therefore been extensive research into lying behaviour in this species. Cows in early **lactation** spend less time lying than cows in late lactation and dry cows, which is probably due to an increased milk yield at this time. The length of time spent lying varies with age and sex: for example, it averages 13 h/day for calves, 12 h/day for bulls and 7-10 h/day for lactating dairy cows (in approximately five periods of 1.5 h each).

The housing conditions in which intensively managed farm animals, such as dairy cows and pigs, are kept can also affect lying behaviour. Lying time of cows in cubicles declines in proportion to the degree of overcrowding, and cows in straw yards lie for longer than those in cubicles. Also, routine farm procedures, such as **artificial insemination**, can increase standing time. In New Zealand, farmers remove cows from pasture during periods of heavy rainfall to avoid damage to the swards, and confine them in concrete yards, where they are deterred from lying on the hard surface and spend most of the time standing.

In recent years, there has been economic pressure for livestock farmers to reduce the amount of space available for their animals (see: **Intensification of animal production**). For example, cubicle (free-stall) systems have been developed for cattle and require each animal to align closely with its neighbours rather than lying in a more random pattern, which occurs in straw yards or at pasture. A cubicle contains a solid bed raised off the floor with partitions to create individual lying areas for the cows. If the cubicle bed is too small for the size of cow, which is increasingly common with the increased size of modern dairy cows, then she will have difficulty lying down or getting up. This leads to leg abrasions and swellings, and cows often resort to lying either half in the cubicle or completely in the passageway. Some improvements in the use of cubicles can be achieved by training calves and heifers to accept a smaller version of the cubicle. When a cow lies down in a cubicle she normally kneels down with one foreleg, then both, and then tucks one hind limb under her abdomen as she lowers her rear end. Thus when lying down the cow eases her centre of gravity forward along a longitudinal axis to minimize the stress on the limbs. Adequate space for forward motion is essential for cow comfort, both when lying down and when rising. An estimate of cow comfort while lying can be made by seeing how much intervention is needed to get a cow up when she is lying. When rising, the cow first raises her forequarters slightly and then her hindquarters, using the outer hind leg primarily for vertical propulsion, then the inner hind leg that was tucked under, the fore leg on the same side and finally the outer front leg.

The style of lying may be affected by a range of circumstances. For example, pregnant cows often prefer to lie on their left side, because the **fetus** dwells in the right side of the abdominal cavity, at least in the latter stages of **pregnancy**. On average, about one-third of cows show a clear preference for right- or left-side laterality. As the cows get older they show less preference for left-side laterality, probably because there is more room in the abdominal cavity and less chance of damage to the fetus by lying on the right side. If there is a slope on the cubicle the cows prefer to lie with their dorsal side uphill. If a cubicle to one side is occupied, a cow prefers to lie with her back next to the cow's back in the adjoining cubicle. If cubicles are positioned end to end with open fronts, as is sometimes advocated to allow adequate lunging space, the cows are reluctant to lie facing each other. In fact they seem to prefer a cubicle with a solid front, which limits lunging space but perhaps provides psychological benefits.

Animals lie either in the sternally recumbent position, that is, on the sternum or breast bone, when they retain some awareness of their surroundings, or in the laterally recumbent position, with limbs and head outstretched. Some animals, such as ruminants, cannot spend long periods in lateral recumbancy because of their need to eructate gases from the rumen at regular intervals. Gravity plays an important part in reticulo-ruminal function and in releasing the gas bubble (normally present in the dorsal sac of the rumen) to the atmosphere via the oesophagus (see: **Bloat**). Calves without a fully developed rumen often lie for

some time in the laterally recumbent position. Beef cattle that are very fat occasionally have difficulty in maintaining a sternally recumbent position, and may roll over on to their side. Sheep may roll on to their backs and be unable to get up if their wool and conformation

P.394

are such that they have relatively flat backs - a feature favoured by many breeders.

When animals lie down, they should be prevented from lying in their own excreta, otherwise they will suffer from problems associated with the acidity and constant wetting of the foot, such as hock burns in poultry and 'slurry heel' in cattle, respectively. One way of removing them from their excreta for at least part of the day is to build raised beds for the animals to lie on. The development of cubicles or free stalls has had a major impact on reducing **mastitis** in dairy cows, caused by contact between the cows' teats and faeces. There are many different types of cubicle divisions available, all attempting to effectively separate the cows while minimizing the hindrance to their movements caused by the hardware.

One modern design that allows some space sharing by virtue of the absence of a bottom rail at the back of the cubicle is the Dutch Comfort design. If there is a bottom rail it should be about 50 cm from the cubicle base to avoid cows becoming trapped underneath. Front rails, which prevent the cow moving too far into the cubicle and becoming trapped, should be either near the floor (<25 cm from the floor) or on the top rail; otherwise the rail will impede a cow's rising. In Dutch Comfort cubicles the front hoop should not be wider than 35 cm, or small cows can get their shoulders stuck. Some cubicles should always be able to accommodate the largest cows in the herd.

A variety of bedding materials can be used to increase animal comfort on raised beds, which should absorb the force of the animals lying down and also absorb any urine deposited in the bedded area. Dairy cow cubicles may have a neck rail positioned perpendicular to the divisions, attached to the top rail 45 cm from the wall. This forces the cow to reverse out of the cubicle as she stands up and prevents the bedding being soiled. If cows are not able to stand fully in the cubicle, they will often stand half in and half out, which may increase stress to the hind feet. This is common in subordinate cows, which use the cubicle as a place of escape.

Bedding material should also have insulatory properties for animals, particularly young, non-ruminant animals kept in low temperatures. For example, the lower **critical temperature** can increase from 8°C for a calf on dry straw to 17°C for the same calf on dry concrete. When the temperature falls outdoors, cattle lie down for longer in order to reduce heat loss from the underside of the body.

Tethering animals often restricts their lying, at least for the first few weeks, when they display more intention of lying but fewer actual bouts of lying, and when stress levels are increased. Lamé animals spend more time lying (to release the pressure from standing) and less time feeding, possibly to avoid competitive interactions with others.

Although species like the horse have anatomical adaptations that allow them to conserve energy and doze while standing up, they must lie down in order to enter REM (rapid eye movement) sleep. Lying behaviour in this species has been shown to be affected by factors such as the bedding substrate and the novelty of the environment.

M

Macaque

Macaques are what are typically known as ‘Old World’ **monkeys**. There are 15 species including the Rhesus (*Macaca mulatta*), crab-eating (*Macaca fascicularis*), stump-tailed (*Macaca arctoides*), Japanese (*Macaca fuscata*), Bonnet (*Macaca radiata*) and Barbary (*Macaca sylvanus*). They are naturally found almost exclusively in Asia. Primates belonging to the family Cercopithecinae (which includes macaques and vervet monkeys) are gregarious, inquisitive, noisy and often live alongside humans, scavenging on their crops and waste.

Macaques are commonly used in research to study normal complex neurophysiological processes, e.g. **vision** and **hearing**, and **disease**. Macaques can be trained to carry out various tasks, and this has led to them being trained to cooperate in experimental work and provide valuable insights into nerve function. Training can also reduce the effect of experimental **stressors** on them, such as the taking of a blood or urine sample. In **captivity**, cramped conditions predisposed macaques to fight and so single housing them in barren cages became commonplace. However, particularly since the late 1990s, efforts have been made to house them in harmonious groups in enriched surroundings, and fighting has been markedly reduced, though not always eliminated, as with any grouped social animal.

(DBM)

Magnetoception (magnetoreception)

Magnetoception is the ability to detect magnetic fields and often involves cellular collections of magnetite, possibly in association with other specialized structures. The capacity for magnetoception has been identified in a wide range of species, ranging from invertebrates such as honeybees, fruit flies and lobsters, to some species of cartilaginous and bony fish (e.g. sharks and salmon), **reptile** (turtles and crocodiles) and bird (pigeons), but is less well documented in mammals, although it is suggested that **cattle** tend to align themselves towards the magnetic poles as a result of magnetoception. Magnetoception appears to be associated with the navigation required for migratory or **foraging behaviour** over relatively large distances for the species concerned, although it is often only one of a combination of cues used to aid orientation.

Maladaptive

The term ‘maladaptive behaviour’ is often used in relation to **problem behaviour**, but the two should not be considered synonymous, and a further useful distinction can be made between them.

Maladaptive behaviour is behaviour that is not well adapted (biologically appropriate) to the circumstances, and within the context of the captive animal may arise as a result of attempts to behave in an adaptive way in an environment to which complete adaptation may not be possible. For example, an animal may continue to perform **appetitive behaviour** for prolonged periods if its consummation is frustrated and there is insufficient **motivation** to undertake an alternative activity. The resulting behavioural display may seem inappropriate or ‘**abnormal**’, but it cannot be assumed in these instances that the underlying mechanism is afflicted by a pathological process and therefore not functioning as it should. The animal may be operating according to its **phylogeny**, using evolutionary ‘rules of thumb’ that have resulted in the selection of

behaviour strategies that are appropriate given the normal environment for the species. However, when the animal is taken out of that environment, these processes may no longer be 'fit for purpose' or result in appropriate adaptation.

By contrast, the term 'malfunctional behaviour' suggests that the underlying processes are not working as they should. By way of analogy, when a computer malfunctions we tend to think of something going wrong inside it, however a maladaptive computer may be malfunctional or it may alternatively be doing what it is supposed to do (but not necessarily what we hoped it would do when we bought it!). In this case the term 'malfunctional behaviour' should be limited to a description of those actions that are expressions of direct disruption of the nervous system or its normal regulation; i.e. the neural basis to the behaviour has no functional value in any context, e.g. seizure activity or age-related decline in function (**see: Cognitive dysfunction**). Such behaviours are the result of a genuine pathology.

With these definitions it follows that malfunctional behaviour is also, by definition, maladaptive. Most problem behaviours appear to be adaptive responses or maladaptive behaviours that are not malfunctional, but are considered inconvenient to the carer or other interested party.

Malnutrition

At its most chronic, malnutrition is commonly due to an inadequate feed supply leading to the classic symptoms of **starvation** in humans, leading in turn to **kwashiorkor** and **marasmus**, or deficiency of one or more essential nutrients. Examples include: (i) lack of vitamin C, leading to scurvy in guinea pigs; (ii) lack of lysine and methionine, leading to

reduced growth in pigs; and (iii) phosphorus deficiency in livestock, leading to chewing of wood, bones, soil and other items, a phenomenon known as **pica**. In addition to these chronic effects in farm and **laboratory animals**, other examples of malnutrition include acutely inappropriate feed, leading to illness or death, and short-term feed deprivation resulting in hunger. There are also diet-related risks in high-producing animals: for example, **culling** due to **lameness** is higher in more productive sows, associated with their increased susceptibility to conditions such as osteomalacia (related to calcium deficiency) arising from the physical limits on the amount of feed a sow can eat to replenish minerals lost during **lactation**.

P.396

Lack of feed

Natural disasters such as fire, flood and drought are an integral part of pasture-based livestock production around the world, and their impact on animal **welfare** can be catastrophic. For example, in a drought in the early 1900s in Australia, cattle numbers fell from 4.0 to 2.5 million and sheep numbers fell from 10 to 7 million and, while some animals would have been deliberately de-stocked, many would have starved to death. The main welfare issue in assessment of drought-affected animals is the subjectivity involved in deciding how much weight an animal should be allowed to lose and whether to provide supplementary feed or sell or agist stock. At what point, and at what condition score, does a hungry animal, losing weight, and maintained on a sub-maintenance ration, become an animal whose welfare is at serious risk? The interactions between economic viability, stocking rate, land degradation and animal welfare are complex and conflicting. Providing conserved fodder or supplements rather than reducing stocking rates or selling animals has the potential to have the greatest adverse impact on welfare if a drought persists.

Flood and fire can both directly kill animals and have major adverse indirect effects. Crops can be washed away or burned, remaining pastures can become contaminated or inaccessible and conserved fodder can be destroyed. The most serious welfare issues are likely to be feed shortages and an increased incidence of **disease**.

While lack of feed is commonly associated with natural disasters, it can also take place in conventional farm production. For example, chronic underfeeding occurs in flocks of both broilers, due to competition for limited feed, and laying hens, due to feed intake being restricted by **aggression**, and results in stunted birds with long-lasting effects on growth and **egg production**.

Inappropriate feed: toxic plants

Many plants and fungi biosynthesize chemicals that are toxic to animals. In ruminants, fungal (myco)toxins in the soil or pasture are suspected of causing seasonal 'ill-thrift' and reduced weight gain, despite an abundance of feed. An example is perennial ryegrass (*Lolium perenne*) staggers, which occurs in sheep, cattle, horses, alpaca and deer due to alkaloids produced by endophytes, including the neurotoxin lolitrem-B and the vasoconstrictor ergovaline. Stock **grazing** affected pastures develop a fine head tremor that progresses to nodding, trembling, incoordination and jerky, exaggerated limb movements with a stiff-legged gait. Affected stock can go down on one side with their legs extended. Left alone they can recover, regain their coordination and get up and resume grazing. When **death** occurs, it is usually by either misadventure (drowning in troughs, dams and gullies or attacked by predators) or wasting due to recumbency, starvation and/or dehydration, with many downed stock requiring **euthanasia**. Some sheep may be found dead overnight after grazing toxic pastures for prolonged periods. Drowning can occur due to the effects of ergovaline on increasing body temperature; this encourages affected animals to seek water. When removed from the toxic pasture animals return to normal movement in 1 to 3 weeks.

Feed restriction

The major effects of short-term feed deprivation, as can occur during **transport**, are dehydration and tissue catabolism. Sheep and cattle appear to tolerate such feed and water deprivation extremely well. Typical live weight losses in sheep range from 6 to 10% of body weight during road transport up to 24 h, and from about 3 to 11% in fasted cattle. Deprivation of food and water for 48 h over a wide temperature range did not induce cortisol or **prolactin** release in sheep, and fasting of cattle for 72 h did not affect plasma cortisol, **catecholamines** or haematocrit, suggesting a lack of **stress** effects. However, pigs that have been without feed for 3 h appear to suffer from travel sickness, as indicated by retching and vomiting. In contrast to this often single or occasional period(s) of short-term feed deprivation, for some farm animals - notably breeding sows and breeding chicken meat birds - there is an ongoing and deliberate feed restriction.

It is generally agreed that pigs should be restrictively fed during **gestation** at a level of about $1.5 \times$ maintenance, which is about $0.6 \times$ *ad libitum* intake. One reason for this restriction is that high levels of feeding during pregnancy can compromise piglet growth during lactation. While the level of feeding is sufficient for maintenance, some growth and fetal development, it also results in pigs being highly motivated to feed. **Operant conditioning** studies in which sows work for a feed reward suggest that they are hungry for a considerable period of the day. Stereotypic behaviours that can occur in these restrictively fed pigs may be due to a frustration of feeding **motivation**, as they are reduced by additional feed.

Similarly, restricted feeding (about $0.5 \times$ *ad libitum* intake) is the usual practice in broiler (meat chicken) breeder management to maximize reproductive performance. The breeding bird is a similar weight at about 18 weeks of age to a meat bird at slaughter (less than 7 weeks of age). Welfare concerns arise from changes in bird behaviour, including abnormal oral behaviours such as pecking at non-food objects and increased drinking activity. Nevertheless, slower growth has welfare benefits such as improved **immune system** responsiveness and disease resistance, fewer skeletal problems and considerably lower **mortality**. While it is generally agreed that *ad libitum* feeding adversely affects the welfare of both pigs and broilers, there is no agreement on what level of feed restriction is unacceptable.

Marasmus

Marasmus is a form of combined protein and energy **malnutrition** resulting in emaciation and less extensive oedema, which is more typical of the more life-threatening **kwashiorkor** (arising as a result of just a protein deficiency). Marasmus is more typical of the unweaned animal, arising as a result of inadequate milk production from the mother due to her own malnutrition.

(DSM)

Marine mammal

The history of the relationship between marine mammals and humans goes back as long as people have lived near water. Marine mammals exist in a web of cultural, religious, legal, recreational and economic relationships with humans. The varying nature of human impacts on and interactions with marine mammals, from **hunting** to rehabilitation, requires multifaceted approaches for effective management and coexistence.

Three orders represent the 119 taxa of present day marine mammals. Pinnipeds, meaning 'fin-footed', are aquatic carnivores including seals, sea lions and walruses. Taxonomic classification is further broken down into Phocidae or 'true seals' (the majority of seal species), characterized by the lack of external ears, Otariidae or 'eared seals' (sea lions and fur seals) and Odobenidae (walruses). Though pinnipeds are fourlimbed, they rely mostly on their front limbs for steering while in the water. Although all species of pinnipeds rely on dry land to some degree, such as for **breeding** and bearing of young, their fat-insulated and streamlined bodies are largely adapted to life in the water.

Cetaceans, including the largest mammal on the planet, the blue whale, consist of whales, dolphins and porpoises. All cetaceans are fully aquatic and have special adaptations for their marine life history, such as blowholes to assist in fast gas exchange, vestigial back limbs and internal sex organs creating a fusiform body shape and, for many species, **communication** systems such as **echolocation** that take advantage of their fluid environment. Cetaceans are classified depending upon their method of feeding. Species possessing teeth, including toothed whales (sperm whales), dolphins and porpoises, are classified as Odontoceti, while species that rely on keratin plates of baleen (such as humpback whales) are classified as Mysticeti.

Also fully aquatic are the Sirenians, consisting of all manatee and dugong species. Slow moving, and relying on dense layers of fat insulation, these herbivorous species are confined mostly to coastal marine areas and inland river and estuary systems, and are not able to survive in cold water temperatures. Two species from the order Carnivora are considered marine mammals because they have crucial aspects of their life histories that rely on an aquatic environment, such as for **feeding** or **locomotion**: the polar bear (*Ursus maritimus*) and the sea otter (*Enhydra lutris*). These two species are the most terrestrial of all of the marine mammals. The common thread among all marine mammals is that they have evolved both anatomically and behaviourally to the constraints of an aquatic life. Dependence on water varies, with pinnipeds having

both a terrestrial and marine life history strategy, while cetaceans and sirenians are constrained to a solely aquatic ecosystem. Many species, particularly cetaceans, are characterized by long life histories and slow reproductive rates.

Marine mammals have been kept in captive facilities in North America and Europe since the 1860s. Their charismatic image, coupled with their ability to be easily trained for a multitude of behaviours, made them a hugely popular attraction at recreational marine animal parks. Modern behaviour modification techniques became standard within training regimes by the 1970s, influenced largely by the positive reinforcement techniques popularized by Karen Pryor's work with captive bottlenose dolphins. While there are a few species of predominantly solitary marine mammals commonly maintained in **captivity**, such as polar bears, the majority of captive species are characterized by complex social structures.

The dynamic interactions between varying age groups, sexes and related individuals could be considered one of the primary concerns in the maintenance of suitable captive environments. This concern is a growing topic of debate in discussion of **welfare** issues surrounding captive marine mammals, especially as more information is obtained from field studies on the **ecology** and behaviour of wild populations. On the most extreme side of the debate over welfare issues is the argument that the social structure, environmental needs and behavioural repertoire of most species make them unsuitable for a captive environment. While particular myths of harmful effects of captivity have been debunked, such as the myth that echolocation in a tank is potentially harmful or a droopy dorsal fin signals depression, there are still valid questions to be raised when designing and maintaining an environment for species that often possess dynamic and complex social needs. Perhaps more so than for most other vertebrates in captivity, technical design of habitats is a crucial issue to be considered in captive welfare, given the risk of various forms of infection and **disease** stemming from water filtration systems.

Along with increasing awareness of social requirements of marine mammals came a greater understanding of the

P.398

psychological needs of these species. A number of scientific studies in captive animals have shown that many cetaceans have cognitive abilities comparable to those thought to be unique to primates. Pinnipeds, sirenians and cetaceans have 'advanced' cognitive abilities, suggesting the importance of a stimulating captive environment.

Among concerns in all captive species, **stereotypies** and other behaviours associated with negative consequences of captivity are observed in marine mammals. However, positive **reinforcement** techniques - which were developed largely with marine mammals - are a source of **enrichment** and stimulation that meets many of the **behavioural needs** of captive species. These applied behaviour techniques have been used effectively to reduce stereotypic behaviour and improve health monitoring and reproductive function. Environmental enrichment programmes are widely used to enhance the well-being of captive marine mammals. Many marine mammals held in captivity, such as dolphins, spend much of their time in the wild searching for food and socializing with **conspecifics**, and are therefore exposed to a variety of constantly changing stimuli. In captivity, needs for stimulation can be addressed in part through social housing and the application of behaviour modification techniques, as well as the creative use of environmental enrichment.

The 1972 Marine Mammal Protection Act in the USA was among the most notable advancements for marine mammal welfare. Before this piece of legislation, there was little monitoring of human impact on wild populations. In addition to regulating hunting and the capture and transport of wild species, the Marine Mammal Protection Act also identified the need for scientific research on marine mammal populations. Increasing scientific knowledge on the ecology, behaviour, physiology and health of marine mammals has applications for increasing standards of care for captive individuals, as well as for the development of effective management guidelines for the **conservation** of wild marine ecosystems.

Escalating human impacts on coastal ecosystems stemming from pollution and recreation intensify the need for judicious management plans for wild marine mammal populations. Behavioural research on wild and captive animals is necessary to increase public awareness, develop wild and captive management strategies and provide guidance to regulatory agencies responsible for developing and enforcing legal aspects of human interactions with marine mammals.

Markers, animal

Individual animals may be identified for legal, practical or scientific reasons. Many identification techniques are available, and the appropriate method for each situation will depend on the species and strain, number of animals in each group, reason for identification and the skill of (and resources available to) the person applying the technique. Some methods can cause discomfort, pain or distress, so the least invasive system should always be chosen (see Table M.1).

Market

A market is a centralized area where producers (farmers) or dealers bring livestock for sale. These may be young, breeding or milking stock that will be sold to other farmers (sometimes via dealers) or animals that are ready for **slaughter**. Traditionally, and in undeveloped countries, there are many small markets, often simple street markets, that serve a local area so that animals travel for short distances and times. This reduces **transport stress** and the risk of disease transfer. Owing to the economies of scale and centralized processing and distribution of meat for supermarkets, the trend in the developed world is for fewer, larger markets. These subject the animals to long transit times. For example, a dealer might pick up a few animals from several farms and deliver them to a market, where they may wait for several hours to be sold and then have to travel to other farms or have a long journey to a centralized abattoir. Thus 1- or 2-day transits are not uncommon, particularly when animals are traded as commodities between countries and across continents.

Annual fairs are a common way of selling many species, including feral ponies, (race) horses, camels and, in the autumn, ruminants raised on marginal land such as hills and moors. These fairs may be relatively informal, with individual negotiations between buyers and sellers, or they may involve auctioneers and make use of more permanent penning and handling facilities. Live poultry tend to be traded in only very small local (street) markets. The majority of poultry nowadays is kept intensively in flocks of thousands and travel direct to slaughter.

Even in informal street markets and annual fairs where animals are not auctioned, there is generally some form of regulation or overseeing of vendors, who usually need to register and/or pay for their pitch. Animals for sale are often individually recorded and given a sale number. In many countries all animals presented need to be fit for sale, and this is overseen by a veterinary surgeon. Further disease control measures may require owners of animals to have a licence to move them both to and from the market or gathering. The UK has introduced passports for ruminants and equines that need to accompany the animals on journeys. All movements and changes of ownership have to be notified to a central agency. This is in a bid to contain diseases like foot-and-mouth and to safeguard the **welfare** of the animals by limiting the number of journeys they can make, particularly within a short period of time.

In a typical permanent auction market site there are defined areas for unloading and loading of the vehicles that transport the animals, with raised platforms or ramps to reduce the slope of the tailgate and enable the animals to transfer easily to and

P.399

from holding pens. Frequently there are races and restraining devices such as yokes so that animals can safely be identified individually (e.g. to read ear-tag numbers and check whether they correspond with the paperwork). This area requires good lighting, well-designed facilities and skilled **handling** of the animals to ensure good welfare. Equines and ruminants may

have an auction (catalogue) identifying number glued to their rumps - for other species this number is more often on the pen to which they are then moved.

Table M.1. Examples of common identification techniques in animals.

Technique	Comment(s)	Welfare issue(s)
<i>Non-invasive</i>		
Noting physical differences	Preferable on welfare grounds but may be unrealistic, e.g. if marking is a legal requirement	None, unless handling required
Identifying enclosure, e.g. by cage label	Legally required in some contexts, e.g. experimental animals	May necessitate single housing; undesirable for social species
<i>Minimally invasive (should cause no more than momentary, slight stress or discomfort, if competently performed)</i>		
Staining or dyeing of skin, pelage or plumage; clipping of fur, claws or feathers	Temporary identification only	Stains or dyes must be non-toxic and non-irritant; some colours may influence behaviour (e.g. red can be mistaken for blood)
Microchipping	Widely used in many species, including birds, rodents and larger companion or farmed animals	Inappropriate siting can cause discomfort; transponders can migrate
Leg rings, e.g. birds, rabbits; collars, e.g. carnivores, primates, farmed animals	Wide variety of rings and bands is commercially available	Rings and collars must be of correct size (and frequently checked in growing animals); colours can influence behaviour in some species
Heat-branding of horns or hooves	Semi-permanent; cannot be used until horns fully grown in some species	Can be stressful, but should not hurt if carefully done
<i>Invasive (will cause pain and distress that should be minimized)</i>		

Tagging, e.g. ear, wing	Tagged animals may be identified at a distance	Tags should be as small as possible and sited to avoid catching or tearing
Tattooing	Pigment is deposited in the dermal layer of the skin; marks can fade in some species	Causes pain and soreness
Freeze branding	Destroys melanocytes, producing white fur	Causes acute discomfort
Ear notching/punching	May be combined with biopsy in transgenic animals, instead of tail tipping	Painful, risk of tearing in small animals
<i>Seriously traumatic (will cause severe pain and/or affect normal behaviour or survival)</i>		
Toe clipping	Mainly rodents and amphibians	Very painful, reduces survival in field
Web punching	Aquatic animals	Painful mutilation; risk of infection
Heat-branding of skin	Produces permanent scar tissue	Extremely painful; illegal in many cases, e.g. cattle in the UK

At a livestock market, the animals may be sold either via private treaty, which is common in small markets and in the Netherlands, or by auction. The most common practice is to auction groups of animals such as pigs, calves and sheep with potential purchasers moving to the pen containing the animals. Unless they need grading by size, quality or appearance, the animals will move directly to and from this one pen when arriving and departing the market, and this method is comparatively less stressful and also reduces the risk of disease transfer. Larger animals such as finished cattle, dairy cows or even groups of store beef cattle may be moved several times and then driven around a central static auction ring during bidding by potential purchasers.

This method of sale is more convenient for humans and often quicker, but with welfare implications for the animals, which often experience social stress from isolation if handled singly and from mixing with strangers. Additionally, they will experience the novel sights and sounds of the auction ring, which they may find frightening. The number of movements is increased along with the potential for injury either from the hardware (gates, posts, etc.) or from being hit by **goads**. Calves may be penned in groups but moved singly into a mobile auction ring that is moved to be adjacent to their pen. After sale, animals that are sold in groups usually remain with their cohorts when moved to the purchaser's vehicle. Other animals such as finished beef cattle and cull cows are often grouped in pens with strangers before being loaded for transport. Animals

for export may need formal examination and certification of **fitness** by a veterinary surgeon. To reduce disease risk, many

countries require transport vehicles to have litter material disposed of and to be washed and disinfected on the market premises between each load of animals. An area with suitable facilities is provided for this purpose.

Cattle have been shown to become more tired and thirsty (Jarvis *et al.*, 1996) and to sustain more bruises (e.g. Weeks *et al.*, 2002) when they have been through markets. Meat quality problems are often associated with the welfare issues of stress, **hunger**, thirst and poor handling, and tend to increase with total transit time. Thus passing through a market does not inevitably cause problems but, by adding to transit time and increasing the number of handling events, this usually increases the risk of poor welfare and disease. For this reason, as well as consumer perception of animal welfare, meat retailers and fast food outlets are increasingly wishing to avoid markets in their sourcing of meat (Murray *et al.*, 2000).

Murray *et al.* (2000) point out that a wide range of journey structures and complexity is found with all marketing methods. They also note the potential of electronic auction systems for reducing marketing costs, but that their uptake by industry has been limited and potential welfare benefits little researched. Electronic auction systems enable all potential buyers to simultaneously log on remotely and view images (usually real time) of the animals for sale. They can bid electronically, with an auctioneer controlling the sale. Purchasers still tend to prefer to examine an animal in the flesh in three dimensions and so continue to visit markets or farms even though this is more time consuming.

Most animals find handling stressful, unless, like the dairy cow, they are habituated to daily handling. The number of times an animal is handled and the nature of the handling are both important. To reduce stress:

- Handling should be minimized.
- Facilities should be well-designed (e.g. races should curve and have solid walls to prevent distraction and to encourage animals to move forward easily, and there should be no sharp edges, in order to reduce injuries).
- Human handlers should be sympathetic, experienced and trained to consider animal well-being (Grandin, 2000; Weeks *et al.*, 2002).

If handling is poor, animals may baulk, slip and fall, experience **fear** and stress and be more likely to be goaded and hit, leading to **pain** and injury. The nature of the animal also affects its reaction to handling. Certain breeds of pig such as the Pietran have the so-called halothane gene, which is associated with excitability and a stress response to handling and transport. Slaughter animals from these breeds tend to produce meat with quality problems such as pale, soft exudative flesh (**PSE meat**), and thus the live pigs are not sold via markets. Similarly, bulls are more excitable and stressed by handling and thus are comparatively rarely sold via markets, in part to avoid stressing them and the associated chance of their meat being dark cutting. Several studies have found gender differences in response to marketing (see Weeks *et al.*, 2002).

A further issue concerning animal welfare at markets is that of disease. The stress associated with passing through a market can reduce immune function. Concurrently, animals are exposed to a greater variety and number of infective agents than they would be if transferred directly from one farm to another or to the abattoir. It is well known that calves that have come from a market are less healthy during rearing than those transferred directly between farms. The practice of hawking sheep from market to market all over the country to make incremental profits was a major factor in the rapid spread of foot-and-mouth disease in the UK in 2000. Quite aside from the ethical implication of treating sentient beings like commodities, the practical consequences were to have farreaching impacts on both human and animal welfare, as thousands of healthy as well as sick animals were slaughtered in a bid to contain the disease. Markets also ceased trading. Following on from this, a standstill period was introduced whereby animals could not be moved again for a specified number of days (initially 20 and now 6).

Worldwide there is considerable variation in the amount of regulation associated with the marketing of animals. Some countries have unrestricted trade, and a few have detailed legislation and codes covering facilities, handling and **health** and welfare issues. Many multiple retailers and restaurant chains have codes that they apply across countries, and these may have an impact on the marketing of animals to some degree.

Marmoset

The New World **monkeys**, marmosets, **tamarins** and Goeldi's monkey belong to the family Callitrichidae, subfamily Callitrichinae. There are 22 species of marmosets in four genera: six species of *Callithrix* from the Atlantic forest and, from Amazonia, 14 species of *Mico*, one species of pygmy marmoset (*Cebuella*) and one species of dwarf marmoset (*Callibella*). *Cebuella* is the smallest higher primate, weighing around 130 g, *Callibella* weighs around 150-185 g, while other marmosets weigh 300-450 g. The common marmoset (*Callithrix jacchus*) is used extensively in biomedical research and is the focus here.

Marmosets have little sexual dimorphism, are diurnal and arboreal and can live to over 15 years. Sexual maturity is reached at 15 months. In the wild, group size is usually around eight to ten. The basic unit is the family, with one **breeding** female (occasionally two). The father and offspring help to

P.401

rear the young, usually twins. Offspring destined to breed in captivity should remain in their natal groups until they have had experience with at least two sets of offspring, as parental care is learned (**see: Altruism; Parental behaviour**). Marmosets scent-mark territories and are aggressive to neighbouring groups, so physical or close visual contact between captive groups should be avoided. Behaviours such as tail-raised present are displayed when threatened, and a variety of other postures, facial expressions and **vocalizations** can be used to monitor **welfare** (Stevenson and Poole, 1976).

As **gummivore-insectivores**, marmosets have specialized teeth to gnaw trees for induction of exudate production. Given the dental and intestinal adaptation to gum feeding, it is recommended that marmosets are given gum in such a way as to encourage gnawing. The diet should also contain fruit, vegetables, eggs and some animal matter, together with vitamin D₃ if there is no natural light, to maintain healthy animals.

Marmosets are quadrupedal, but are also adapted to vertical clinging and leaping, using their claw-like nails to grip supports. Enclosure furnishings should allow marmosets the opportunity to grip (e.g. rough surfaces) and include a variety of orientations. Platforms or ledges on which the marmosets can sprawl out for **grooming** interactions are important. In the wild, marmosets **sleep** huddled together in tree forks or in dense tangles of vines and leaves, and a secure place for sleeping is important in captivity.

Mastitis

Mastitis is an inflammation of the mammary glands, with the most common cause of infection being bacteria that enter the mammary gland through the teat canal. Mastitis is a problem for the dairy industry in particular (**see: Cattle; Lactation; Milking**), and the control of bacteria that cause mastitis is an important component of herd management. The bacterial pathogens that are most frequently involved in causing mastitis can be placed into two categories - contagious pathogens and environmental pathogens.

The major contagious pathogens are *Streptococcus agalactiae* and *Staphylococcus aureus*. These pathogens are generally found on the skin of animals, colonizing the teat and teat canal. Infected mammary glands are the major source of contagious pathogens within a herd and transference is mainly during the milking process. Contagious pathogens tend to cause subclinical mastitis (i.e. no obvious signs of infection), though a high somatic cell count (SCC) in the milk and a decrease in milk yield are indicators of the presence of subclinical infections within a herd.

Environmental pathogens are found within an animal's surroundings and are transmitted through direct contact of the teats with infected areas. Clean and dry beds and passageways remain the most important management factors in controlling levels of environmental mastitis, as dust, water, manure and feedstuffs can all be sources of infection. Coliform bacteria (including *Escherichia coli* and *Klebsiella* spp.) and species of streptococci (including *Streptococcus uberis*) are the primary environmental pathogens. Environmental mastitis generally produces clinical signs such as a hot, swollen udder and clots in the milk, as well as a high SCC.

Cases of clinical mastitis tend to be of shorter duration than subclinical infections, when treated promptly. Unsuccessfully treated cases of clinical mastitis may become chronic, and the infected quarter is then no longer viable. The rate of intramammary infections increases during the dry period, particularly in the days leading up to calving. However, infection does not necessarily spread throughout the whole quarter, and only a few of the milk ducts may be affected.

(LW)

Mate choice

Mate choice, in the most general sense, can be defined as any behaviour that favours the success of one set of an individual's potential reproductive partners over another. Mate choice can evolve in a system when the total **fitness** of an individual is limited by access to mates of a certain quality or to resources provided by particular mates.

In most multicellular organisms, there exists an asymmetry in gamete size: females produce relatively few large eggs, and males produce many small sperm. Typically, females invest more resources into each offspring through gamete production, and also often greater parental care. Males, therefore, can potentially fertilize eggs faster than they can be produced. Thus males are limited by access to females, and females are limited by access to **resources**. This asymmetry in gamete investment means that males are under strong selection to be proficient at searching and competing for mates, and that females should exert mate choice (Clutton-Brock and Vincent, 1991). There are, however, some exceptions to this rule. For example, when both male and female invest equally in feeding, guarding or brooding of eggs or young, both sexes may exercise mate choice. Moreover, in species with high male and low female investment, like seahorses, or when the sex ratio favours males, females may compete for mates and males may reject low-quality females. Here we will assume that the female is the choosing sex, and males are the competing sex.

The sensory and behavioural properties that influence the propensity of individuals to mate with a particular phenotype are considered mating preferences. Mating preference consists of two components, preference function and choosiness. The order in which an individual ranks potential males represents the preference function, and the energy that an individual invests in assessing mates represents choosiness. Mating preferences may be based on a variety of factors. Individuals may select mates based on direct and/or genetic benefits they or their offspring receive from mating with a particular partner. Individuals may also choose mates on the basis of latent perceptual biases: many animals may prefer mates that are louder, bigger or brighter simply because they provide more sensory stimulation (**see: Intersexual selection**).

animal species males defend territories, which can provide females and/or their offspring with protection from predators and competing males, as well as access to food. The female will often assess not only the male, but also his resource holdings, before making a mating decision. Males may also provide nuptial gifts to potential mates during courtship. Such gifts may help to nourish the female or provide her with protection. Furthermore, in species where the male is the primary caregiver, females may choose mates that can provide adequate food and protection for her young.

In addition to direct benefits, some species may choose their mates based on genetic benefits. The good genes theory predicts that individuals will prefer mates with costly and conspicuous traits because they indicate high-quality genes that will be passed on to their offspring. The handicap hypothesis (Zahavi, 1975) predicts that females will prefer males that acquire a trait with a high survivorship cost, since low-quality males cannot support the cost of the handicap and males with the trait will be of high quality. Some traits are thought to be condition-dependent: males vary their expression of a preferred trait to optimize their mating success and survival based on their condition, and thus the expression of the trait is an indicator of male quality. Traits may also be revealing indicators, where all males in the population attempt to express the trait and pay the same cost for the trait, but the condition of the trait is reduced in low-quality males.

In contrast to the good genes theory, the Fisherian runaway selection hypothesis (Fisher, 1930) predicts the evolution of heritable, arbitrary male traits that may provide no information about intrinsic male quality but enable females to produce sons that are in turn selectively chosen by females. Males with the preferred trait obtain more mates, and because their mates tend to be females with a preference for the trait, the genes for the female's preference and the male's trait become linked in their offspring. Females with the preference for the trait benefit because their sons will also possess the trait and will be more successful themselves. This process can be initiated by several mechanisms. For example, females may prefer male traits that are initially favoured by natural selection and become highly exaggerated, losing their natural selection advantage, or traits that mimic stimuli that females are attracted to, thus exploiting pre-existing sensory biases or feature detector for food items.

In addition to selecting a mating partner, in some species females are able to exert mate choice after copulation. By adjusting the size, chemical composition and sex of their eggs after copulation, some females are able to maximize the benefit of mating with a certain male. In species where females mate with multiple males, some can selectively fertilize their eggs with sperm from a particular mate or mates. Even in some seemingly monogamous systems, where females pair with males for one or more **breeding** seasons, females commonly seek extra-pair copulations, and selectively use the sperm from such matings to fertilize their eggs. Furthermore, females of some insect species will store sperm after copulation and will only fertilize their eggs after they have received a nuptial gift. Although such cryptic mate choice occurs after copulation, it is important to recognize that females may choose the sperm donor based on the same models of pre-copulatory mate choice.

The outcome of mate choice depends on the mating preference of an individual and the extent to which it can be expressed. Availability of suitable mates, **intra-** and **intersexual competition** and environment conditions can influence how much choice an individual is able to exert. For example, in some systems, male-male competition may be so fierce that female mate choice is hindered or suppressed by such contests; in other systems, however, females exert complete control over mate selection. In many species, mate choice can be a reflection of the social conditions that an individual is exposed to. Often animals will avoid mating with close relatives or group members, while also avoiding mates that are members of different species or ecotypes. The success of mating depends on the genetic compatibility of the partners, which can influence the number and quality of offspring.

In applied studies, an understanding of mate choice is critical for maximizing success in a managed system. Understanding how, why and when a particular mate is chosen can have important consequences for the success of captive programmes; if proper conditions are not met, animals may either refuse to mate or make poor mating decisions. Similarly, management programmes designed around wild populations must consider breeding cycles and resources required for mate choice for success to be reached.

Maternal behaviour

Maternal behaviour is defined as the pattern of behaviours given by the mother to her dependent offspring or young. These behaviours are often of extreme importance for the offspring's postnatal development and are directed towards their well-being and care. The evolutionary **fitness** of all species depends not only on the reproductive success of parents, represented by the rate of offspring generated over a lifetime, but also on the offspring's survivability rate. Thus the propagation of a species relies on the reproductive competence and successes of both parents but, especially, on the quality of maternal behaviours in mammals - behaviours that are evolutionarily well conserved throughout species.

Because maternal behaviour so often plays such a major role in the physiological and behavioural development of the offspring, the mother has been entitled by others as a 'hidden regulator'. Some of the distinct behaviours that may be shown by the mother include **grooming** or licking, **nursing**, **feeding** and cleaning, in addition to protection and comfort of the offspring. The amount of maternal care and thus the frequency of maternal behaviours performed towards the offspring vary with species. As an example, female primates spend a large part of their lifetime performing maternal behaviour as opposed to the minimal attention provided by rabbit females,

P.403

which spend only a very short period of the day caring for their offspring within the nest; by contrast, in seahorses the male is responsible for the care of the offspring. This entry will focus on the maternal behaviour of mammals, as this is the area of most common **welfare** concern, but the reader is referred to Groothuis and Schwabl (2008) for a recent review of the regulation of this behaviour in birds.

Maternal behaviour is widely understood in rodents, and comprises a complex collection of activities such as nest building, licking, grooming, nursing and manipulation of pups, e.g. sniffing, exploration and retrieval. Female rodents also perform **placentophagia** - that is the consumption of the placenta immediately after giving birth - although this behaviour is not limited to rodents. **Carnivores** (e.g. dogs, wolves) and **ungulates** (e.g. cattle, sheep), along with animals such as hedgehogs and bats, also perform placentophagia. The most relevant explanation for this behaviour is that the placenta contains chemicals involved in involution and recovery of the uterus to its normal state (**prostaglandin**), and facilitation of milk ejection from the mammary gland (oxytocin). In addition, it contains molecules that modify endogenous opioid activity, helping to reduce the pain that arises pre- and post-delivery.

Maternal behaviour is absent during most of pregnancy and is suddenly triggered with oncoming **parturition**. It may be observed initially for a few days preceding labour in some species. Prepartum nest building observed in female birds, pigs and some rodents is a good example of a maternal behaviour that precedes parturition. Therefore, it is suggested that a complex connection and interaction exists between the **central nervous system** and the endocrine system during that final period of **gestation** and parturition. Their association with sensory stimuli generated by the offspring and environmental conditions both play an important role in triggering and maintaining maternal behaviours in the females.

From studies performed in rodents, specific regions of the **hypothalamus**, *stria terminalis* and lateral septum have been implicated as fundamental **brain** areas for the regulation of pup-directed maternal behaviours. Examples of these behaviours include **grouping**, retrieving and providing warmth to the pups and licking their anogenital regions, along with other tactile stimulation. The medial preoptic area of the hypothalamus receives input from various brain areas and is thought to play a role in identification of mainly olfactory cues from the pup, changing the female's motor activity and behaviour performance. Olfactory cues are crucial for the onset of maternal receptiveness and **recognition** of the newborn, in addition to recognition and establishment of mother-offspring bonding following birth.

The fact that the onset of maternal behaviour coincides with birth makes pregnancy and **lactation** endocrine hormones strong candidates for the initiation and persistence of maternal behaviour. During the last few days of pregnancy, endogenous levels of hormones such as **progesterone** begin to decline, while **oestrogen** and **prolactin** levels increase. These factors are believed to contribute to the enhancement of neural activity and beginning of maternal behaviour pre- and immediately postpartum. Oxytocin, an essential hormone for smooth muscle contraction at the time of parturition and milk ejection during lactation, has also been implicated as one of the central mediators of maternal care. It induces investment behaviours and maternal responsiveness when administered to **rats**, mice and ewes. The role of neuropeptide opioids, such as β -endorphin (**beta-endorphin**), during and after birth is controversial, as they may assist in **pain** reduction during labour and play inhibitory and stimulatory roles in maternal behaviour presentation.

The quality of maternal behaviour displayed may also rely on maternal experience. In general, experienced mothers (multiparous) show better maternal care and faster responsiveness to the offspring after birth than does a first-time, inexperienced mother (primiparous). Maternal behaviour in most species is terminated as the mother makes herself less available for the offspring by rejecting them. The actual time point in the offspring's life for terminating maternal care and nursing is determined by cues detected by the mother. For instance, female rats use **thermoregulation** to modulate mother-pup contact. Other factors, such as the offspring's weight and size related to birth, and eruption of teeth or tusks, also play a role in determining the time to separation and **weaning** in the young animal.

Maternal investment

Maternal investment has been defined as any investment or expenditure (e.g. time, energy) generated by the mother for an individual offspring, thus increasing its chance of survival and improving its well-being and reproductive success (Trivers, 1972). This investment relies on the cost of the mother's (or parent's) ability to invest in other offspring, future reproduction and inclusive fitness. The age of the offspring is also a factor in maternal investment. Growing offspring become more independent from the mother and thus benefit less from her; however, maternal demands intensify as the offspring become older. Offspring will try to acquire for themselves the maximum gain from maternal investment. However, at the same time, the mother must restrict maternal investment to no more than that absolutely necessary in order to successfully rear offspring and yet maximize her own future reproductive outcome.

This scenario can sometimes generate conflicts between mother and offspring interests. For example, the maternal care of **cats** and dogs undergoes deviations in the **reciprocity** of investment until the offspring are fully weaned. After giving birth, the mother initiates contact with her offspring. As the young become older, both offspring and mother concurrently initiate contact, primarily through nursing. As weaning approaches, the offspring mostly initiate nurturing from the mother, who may react evasively or aggressively, eventually leading to separation and full weaning.

There is also evidence that investment behaviour promotes reproductive success and increases offspring production. An interesting example is the female lion pride, where if two or more females in the group are nursing cubs, the mothers effectively form a 'nursery' in which they provide cubs with access to one another's milk. This has been described as leading to superior per capita reproduction in adult lionesses grouped in prides compared with paired or solitary females.

Moreover, maternal investment in offspring is expected to vary according to the offspring sex. This is the case when the reproductive success of the progeny is a function of differential

P.404

levels of parental expenditure. Sex-biased maternal investment is observed in several species and happens mostly towards male offspring. In elephants, there is a greater early maternal investment in male calves than in females, because in the highly competitive seasonal mating systems, the body size of adult male elephants is an important factor for reproductive success. Also, seal females invest more in sons than in daughters until weaning and it is unlikely that higher post-weaning investment in daughters would compensate for the higher pre-weaning investment in sons. Mothers provide sons with extra resources because sons have greater implications in offspring lineage, since one male can produce enough sperm to fertilize many more eggs than one female can produce. Thus, parents tend to invest more in the gender that gives them the greatest reproductive pay-off (greater number of grandchildren) with increasing investment.

However, several theories predict that sex-biased maternal investment may vary under specific environmental or maternal conditions, as predicted by the Trivers-Willard hypothesis (Trivers and Willard, 1973). This states that, in some polygynous species (species in which the male mates with more than one female in a single breeding season, such as red deer), maternal investment is biased toward daughters, instead of sons, when the mother is under poor conditions. Social rank or female dominance status can also affect the sex of offspring generated, with dominant females birthing more sons and non-dominant females birthing more daughters. This is found in captive Japanese macaques (*Macaca fuscata*), where high-

ranking mothers show a significant male-biased sex ratio with greater investment towards male infants, spending more time in contact and carrying them for longer than female infants.

Maternal-filial bond

Filial **bonding** or **attachment** is defined and mediated by the propensity of offspring to seek proximity and contact with their mother in preference to other objects or **conspecifics**. Neonates search for stimulation, such as physical contact, from the mother, which fulfils their expectations and contributes to their psychobiological balance. They also seek out resources from the mother to meet their physiological needs, such as warmth or nourishment. Early interactions between mother and newborn provide the basis for all subsequent interactions and bonding formation, as they have the ability to associate positive experiences with particular stimuli. In mammals, most stimuli are provided while animals are suckling, which is the foundation of maternal care. A robust indication of a proper bonding between offspring and mother is the presence of behaviours involving maternal leadership, assistance and training and, ultimately, cooperation towards offspring.

The establishment of filial bonding in sheep relies on the success of the first suckling bouts, suggesting that the **colostrum** (the first milk secreted by an animal coming into lactation, especially rich in maternal antibodies) ingested by the young immediately after birth facilitates the development of a preference for the mother. It has been shown that lambs receiving colostrum within the first 12 h after birth show a preference for their mother, while those ingesting saline do not. This confirms that maternal contact, effectively intermediated by feeding, is necessary for early associative learning and subsequent establishment of the mother-offspring affiliation. Offspring of group-living species are required to rapidly discriminate and bond to their own mother to maximize chances of survival. Olfactory cues are one of the most important mediators for mother-offspring recognition, facilitating maternal responsiveness, and they play a main role in establishing mother-infant bonding. Maternal recognition is reciprocal and, in general, alien mothers in the group will reject nursing and caring for young that are not their own. Under some circumstances, females may even be aggressive towards unfamiliar young animals.

The natural weaning process generally involves gradual separation of the mother and offspring; however, this event does not necessarily lead to the disruption of the maternal-filial bond. Calves of a semi-wild cattle herd, naturally weaned at the age of 7 to 14 months, do not show signs of impairment in the affectionate bonds with their mothers post-weaning. Cows, while nursing newborn calves, affectionately groomed older offspring that had already been weaned some time previously. In fact, the pre-weaning bonding between mother and offspring plays a major role in the foundation of the herd's cohesive social structure. Evidence of filial attachment post-weaning has also been found in guinea pigs. Physiologically, affiliative behaviours such as maternal care, grooming, protection and formation of a social bond with offspring are believed to be mediated by hormones such as oxytocin, **vasopressin** and endogenous opioids.

Maternal deprivation

Early adverse experiences can cause long-term psycho-physiological and neuroendocrine alterations in young animals that are carried on into adulthood. The magnitude of these effects is proportional and depends on the time (in life) of exposure (including stage of central nervous system development), duration of **stimulus**, and type and severity of the experience. Therefore, converse to maternal presence, early maternal deprivation, an **aversive** experience, negatively interferes with the proper development of both psychobiological and neuroendocrine regulatory mechanisms of a young animal. It is also expected to affect the young's behavioural responses under stressful situations.

The development and responsivity of the **hypothalamic-pituitary-adrenal (HPA) axis**, the main regulatory mechanism of **stress** response, is modulated by maternal behaviour. As previously reported in rodents, the amount of time the dam spends performing behaviours such as grooming and licking is inversely correlated with stress responsiveness in adult animals. Therefore, the ability of animals to cope with stress in life has been shown to be correlated to the amount of maternal care received early on in life. Animals subjected to early maternal deprivation show neuronal deficits and behavioural changes when exposed to stressful situations like social **isolation**. In addition, animals present **neophobia** when subjected to **fear** tests (e.g. novel open field) and evidence of impairment during cognitive performance (e.g. Morris water maze) or social recognition tests.

Maternal deprivation affects the individual's behavioural responses by eradicating the environmental predictability and controllability provided by a maternal presence. **Abnormal behaviours** are frequently observed in an animal subjected to artificial weaning, which, in other words, represents premature

maternal deprivation. Young pigs perform abnormal behaviours such as excessive chewing, sucking other animals and

behaviours resembling massaging of the maternal udder (such as **belly nosing**), reflecting distress caused by maternal separation. Pigs also show greater levels of aggressive behaviour compared with pigs left for longer periods with their dams. Moreover, maternally deprived young primates show **stereotypies**, which have no apparent biological function for the animal, such as digital or tail sucking and clasping, and rodents present **anxiety** and fear-like behaviours. Higher levels of **vocalization** and restlessness are observed in several mammal species when abruptly deprived of their mothers very early in life.

Maternal rejection

Maternal **rejection** naturally occurs with older animals when the mother separates or hides herself from the offspring in an attempt to wean them. However, it becomes a concern for the well-being of the neonatal offspring when rejection happens shortly following birth. This event typically develops when normal **socialization** or bonding between mother and offspring does not take place. Cleaning of offspring by the mother immediately after delivery is often crucial for maternal acceptance and bonding with the newborn, but human intervention with the dam or the infant, either during delivery or postpartum, can interfere with maternal acceptance. As observed in dogs, newborn pups when removed from the nest, washed and returned to the mother may no longer receive maternal care and be rejected by the mother.

Rejection by the mother occurs in all species, including farm animals, and is most frequently seen in primiparous dams (females that deliver for the first time). In ewes, the incidence of rejection behaviours, such as withdrawal, **aggression** and lack of cooperation with lambs during sucking attempts, declines with maternal experience, thus predicting the behaviour of primiparous ewes in future pregnancies. Additionally, dams with infected or injured udders (e.g. **mastitis**) show greater tendency to reject offspring. Agalactia (absence or failure to produce milk) or hypogalactia (lower than normal milk production) are examples of maternal inadequacy and may be associated with rejection. Maternal inadequacy is characterized by the incapability of a dam to provide sufficient maternal care to the offspring and may result from the dam's undernourishment, poor health, excessive excitability or exhaustion due to dystocia (difficult birth delivery).

Rejection by the mother causes psychological and physiological distress for young animals, especially when still dependent on maternal care and protection for survival. However, there may be some secondary and long-term advantages for maternally rejected animals. Once maternal support and help are lost, animals are forced to learn by their own means to handle undesired or stressful conditions more efficiently and succeed in searching for resources, such as food and shelter. Captive Japanese macaque infants whose mothers show high rates of rejection are less fearful and cope better with stressful situations in adulthood, suggesting that maternal rejection promotes offspring independence and the development of a less anxious personality.

Mating behaviour and systems

The union of sexually reproducing animals during mating provides the opportunity for genetic mixing. This increases the adaptive potential as compared with asexual reproduction. Females usually produce a small number of gametes that are relatively expensively supplied with a life-support package to nourish the fertilized gamete. Males, on the other hand, produce large numbers of gametes with much more limited survival capacity. Given the increased investment in gamete production, it follows that in most situations greater investment will also be provided by females to increase the chances of survival of the fertilized egg than by males, and so females usually provide most of the parental care (notable exceptions include seahorses). Variation in male mating behaviour appears to be particularly related to the role of the male in rearing young and the defence of females.

For example, many prey species exhibit precocious development, and the amount of parental care is relatively small, most of which can be provided by the female. Prey animals are normally precocious to limit the predation of juveniles. For example, in cattle the only parental investment provided by the bull is to guard the cow during oestrus and prevent her from being inseminated by a rival bull. This minimal investment strategy encourages polygyny (individual males mating with more than one female) whereas in humans, for example, the need for greater parental investment encourages monogamy (an individual male mating with one female). Polygyny in turn causes competition between males for females, which results in **sexual selection** in the males and sexual dimorphism.

Sexual selection in many species is responsible for the increased size and strength of males, particularly in the shoulders, neck muscle and size of horns, antlers or other offensive body parts, which is advantageous for effective combat to secure access to females. The **hierarchy of dominance** so created ensures almost exclusive access to receptive females by the dominant males. However, despite the intense competition between the males to secure access to females, the dominant male does not usually attempt to force

P.406

females to copulate. Males will guard the females, with attempted mounting, and they may show other **appetitive behaviour** such as partial erection and dribbling of accessory fluid. This is because it is in the male's interest to copulate only when the female ovum is receptive, and this information is readily imparted to the male by the female's behavioural signals, unlike humans where it is believed that the primeval female may have attempted to hide her menstrual condition to secure greater rewards from the male in the form of food and protection.

Some mammals also exhibit bisexual behaviour, for example cattle, with both sexes frequently exhibiting hetero- and **homosexual behaviours**. In the case of cows, homosexual behaviour was used in **feral** herds as the main signal to visually indicate to distant **grazing** bulls that the herd contained receptive cows. It is likely that there has also been human selection for this trait for as long as the sexes were kept apart, to indicate when a cow was ready to be inseminated (naturally or artificially). However, homosexual behaviour in cows is probably more than just a signal to bulls or man. It persists even in the presence of the bull and may serve to satiate a cow's sexual motivation over and above the attention paid to her by the bull.

Matriline

The matriline refers to the maternal female line of ancestors of an individual. Since mitochondrial DNA is inherited only from the ovum, all mitochondrial DNA is matrilinear and so the study of mitochondrial DNA can give an insight into the number of founding females within a population. The paternal line of inheritance is referred to as the patriline.

(DSM)

Maturation of behaviour

New behaviour often arises as a result of learning (**see: Conditioning - types of**), but it may also occur as a result of the growth and development of the mechanistic processes regulating its expression, i.e. as a result of its maturation. This development reflects a largely genetic regulation of the underlying maturational process, since it occurs independently of experience, i.e. experience is not a necessary condition for its expression, although experience may affect its exact timing. Thus males of several species reared in the presence of sexually mature females express sexual behaviour at an earlier age than **conspecifics** reared in **isolation** from females, even without direct access to these females. This phenomenon is thought to be mediated largely through primer **pheromones**, but other stimuli may also play a role. Perhaps the most obvious examples of behaviour that develop as a result of maturation are **sexual behaviour**, **reproductive behaviour**, **maternal behaviour** and paternal behaviour; however, it is now recognized that many behaviours mature at specific times during development, according to their adaptive value at a given age.

In some species behavioural patterns may be seasonal due to the development and atrophy of supporting physiological structures, such as the **gonads**, which regulate the production of sex steroids and sexual behaviour as a result. Some consider this cyclical change in the underlying processes that facilitate the behaviour to be a form of maturation while others do not.

Some argue that concepts like maturation tend to bias the thought and study of animal behaviour towards the idea that animals take time to become fully functional beings (i.e. are initially immature), rather than viewing them, in normal circumstances, as fully functional beings according to the **ecology** of their life stage at any given time. For example, from a biological perspective, it is highly **adaptive** for a young animal not to engage in sexual behaviour and to direct available resources to growth and social development.

Other issues relating to the concept of behavioural maturation also relate to the idea that behaviour - rather than the underlying systems - matures. Thus, although **sensitive phases** tend to be thought of as times of particular sensitivity to certain types of learning (and so not related to behavioural maturation), they can also be considered times at which the maturation of particular types of behavioural response occur (**see: Development - behavioural**), since this is a time of maturation of the relevant parts of the nervous system. Thus, in the absence of exposure to certain stimuli at these times, a particular behavioural pattern becomes established that is relatively enduring due to the mechanistic organization (maturation) that occurs in the **central nervous system** at this time in relation to this particular function. For example, during the **socialization period**, **avoidance behaviour** towards unfamiliar individuals may mature as a result of lack of exposure at this time.

However, the process of **socialization** towards others does not occur as a result of maturation at this time, but rather as a result of experience during this phase of maturation of the nervous system. From this perspective, behavioural maturation is simply the default response that develops over time in the absence of experience. The concept of behavioural maturation may therefore be seen by some as a relic of the nature-nurture debate or the ethological versus psychological approach to the study of behaviour, rather than as a more progressive approach, which is a synthesis of these paradigms.

Measures of productivity

Many modern, intensive farming methods aim to maximize production by increasing the numbers of animals kept while reducing the costs associated with this task. Productivity is measured in relation to herd or flock production, while **welfare** is assessed in terms of the individual animals.

There is evidence that poor farm animal welfare may adversely affect production in a number of species. For example, stockmanship (see: **Stockperson**) is a variable that is known to be associated with production. **Fear** of humans can provoke a **stress** response in many species, which may lead to poor welfare and performance. In contrast, there are also examples where poor animal welfare does not decrease overall production. A broiler unit may maintain high levels of

P.407

production by using fast-growing strains of birds. However, the welfare of the individual birds may be poor, as reflected in the levels of **lameness** and breast blisters.

Commonly used measures of productivity include **growth rate**, disease incidence (**morbidity**), **culling** and **mortality** rates. Fertility parameters and data pertaining to the final product can also provide insight into the efficiency of a farming unit. Good production, when measured in relation to individual animals rather than a population, may be a necessary, but not a sufficient, indicator of good welfare. For example, **slaughter** data and finishing times may provide a pig farmer with useful information relating to the average rate of growth within the herd. Mortality and cull percentages may reveal the overall efficiency of a broiler unit, as well as indicating the level of **disease**, such as coccidiosis, within the population itself. In a dairy herd, an example of fertility data would be the number of cows returning to service and an example of product data would be milk yield produced by the herd. While these parameters may measure productivity on a farming unit, they may say little about the **quality of life** of the animals. Additional information relating to the management and husbandry of individuals within a population may also be required to ensure good animal welfare.

(AK)

Measuring behaviour

The scientific study of animal behaviour is based on the principle that what an animal does can be quantified objectively. In this way it is possible to increase our understanding of the proximate and ultimate causes of behaviour by using these objective measurements to test hypotheses.

When undertaking a study of the behaviour of an individual or group of individuals, preliminary observations are important. This enables the identification of the behaviours that are relevant to the questions to be asked and the manner in which they will be measured. An **ethogram** may be produced as part of this preliminary work. In addition, the **reliability** (the extent to which they can be consistently measured by the same or different observers) and **validity** (the extent to which they measure what is intended) of the measures can be assessed at this point.

The choice of the measure will depend on whether the behaviour of interest occurs in states, events or bouts. State-type behaviours, such as eating or sitting, occur for a relatively prolonged or meaningful length of time. One can measure the frequency (number of times), latency (time taken to onset) and/or duration (length of time) for which the behaviour occurs during the period of observation. Event-type behaviours, such as discrete **vocalizations** or distinct body movements, occur for a relatively brief period or have durations that are less meaningful, and can be measured at specific points in time. One will usually record the frequency and/or latency with which these behaviours occur during the period of observation.

State- or event-type behaviours can both occur as a bout, which is a period of time during which the same behaviour occurs, whether this is a period of the same state (e.g. a bout of eating) or a period in which the same event is repeated (e.g. a bout of discrete vocalizations). One may measure the frequency of these bouts during the period of observation or the duration of time within or between bouts. Another measure of potential interest is the intensity of the behaviour, which is often less well defined but may have some objective **quantitative measure** such as the speed of the movement or the volume of the vocalization. In some instances a **qualitative measure**, e.g. a categorical scale describing the intensity of the behaviour, may be constructed.

Measuring welfare

Measures that reliably reflect the welfare of animals in different situations are crucial as a fundament for decision making in animal welfare legislation, guidelines, etc. Such measurements should translate the state of the animal (whether it is both doing well and feeling well; **see also: Welfare**) into an objective description that can be agreed upon and used by different observers. The commonly used measures of welfare are usually divided into two broad groups: behavioural and physiological.

In some cases, negative mental states are reflected in overt changes of behaviour, such as **avoidance behaviour** that indicates **pain** or **fear**. When using such measures it is, however, important to consider that, due to their evolutionary history, prey species are less likely to show many behavioural signs of poor welfare than predator species. Changes in overall behavioural **time budget** or the disappearance or appearance of behavioural patterns may also be informative about mental states. An animal that is sick often changes its time budget, spending more time inactive and less time on self-maintenance activities such as grooming and eating/drinking. **Abnormal** behaviours such as **stereotypies** and **self-mutilation** are generally considered to be associated with **frustration** of highly motivated behaviours. But since such abnormal behaviours may develop into habits and persist outside the frustrating situation that originally motivated their appearance, it has been argued that the presence of such abnormal behaviours should be considered evidence of poor welfare experienced at some time in the individual's life, and not necessarily an indicator of its present welfare.

Physiological measures of welfare are generally of two main kinds: those indicative of physical **health** and those associated with the reaction to **stress**. Health measures are relevant for two reasons: first, **disease** itself directly affects welfare and, secondly, disease may be the outcome of chronic stress and therefore indicate that the animals have been exposed to a situation of compromised welfare. Stress-related measures reflect the activation of the two main stress reaction systems: the **hypothalamic-pituitary-adrenal (HPA) axis** and the sympatho-adrenal axis. Indicators of their activation include plasma levels of **glucocorticoids** (cortisol and corticosterone) and **catecholamines** (adrenaline and noradrenaline), as well as cardiac output (**heart rate** and **blood pressure**). **Corticosteroid** level is the most commonly used measure of acute physiological stress. Measuring the plasma level of the hormone requires blood sampling, which may in itself be a

P.408

potent **stressor** and so potentially influence the results. With a delay of minutes or hours, circulating corticosteroids can be found in body fluids that can be collected through less invasive methods, such as saliva or urine. For research purposes, telemetry is increasingly used to measure cardiac output and temperature non-invasively in animals that have been equipped with a microtransponder.

When using these physiological measures it is important to note that they are indicators of acute stress or **arousal**, i.e. the body's reaction to an environmental challenge, and that they do not indicate whether that arousal is experienced as **aversive** or as positive. Whereas the levels of circulating hormones and cardiac output are effective measures of acute stress, they are less useful in situations of chronic stress, as feedback regulation systems often return to near-normal levels. Indicators of chronic stress include changed responsiveness of the HPA axis, immune suppression, cardiovascular diseases and reduced growth.

More recently, interest has grown in the behavioural and physiological indicators of **positive welfare** states such as 'happiness', which include behavioural variety, the occurrence of **play** and the levels of biochemicals such as **oxytocin** and **endorphins**.

Statements about the welfare of animals may also be based on information about the system or situation the animals are in, rather than on measurements carried out on the actual animal. Studies of animals' **preferences** for different environments or resources and how much the animals are prepared to work for these are often used in animal welfare research. If an animal persists in working for access to a resource, even though the workload is increased, it can be assumed that this resource is important for the animal and that its welfare will be strongly affected by whether or not the resource in question is available.

The methods chosen to measure welfare depend on the applications for which the measurement is intended, which in turn may determine the amount of resources available and who will carry out the measurement. In research, there will usually be only one person to carry out the measurement and there is usually demand for a detailed picture of welfare that can be obtained through repeated assessments. In on-site auditing, many different observers will have to carry out assessments that should be reliably comparable, and often the assessment can be carried out only once at each site.

The welfare of an animal depends on many different aspects of its situation (whether or not it experiences pain, **hunger**, thirst, **fear**, **boredom**, etc.), and it is generally agreed that a correct measurement of welfare must account for this complexity and include parameters of different types. It is also important that the different views of animal welfare are accounted for, especially when welfare measurements are used for official purposes such as legislation. However, when welfare measurements are to form the basis for decision making, it is often difficult to handle a complex description that includes many different measures. One way of making this description more operational is to integrate the different measures into a single value, such as an index of welfare. In such an index, different aspects can be given different weights to reflect their assumed importance for animal welfare, and each constituent can be attributed a threshold value. The latter may be important in avoiding a situation that involves grave deficiencies in some aspects, but that is nevertheless given an acceptable overall score because these deficiencies are counterbalanced by positive results in other aspects.

Medicines - traditional, complementary and alternative

Increasingly, animal owners are seeking alternative and complementary options for **health** and behavioural problems. Alternatives include traditional Chinese medicine (TCM), acupuncture, homeopathy, herbal medicine, T touch, flower essences, nutraceutical medicine and others. Like many of the psychotropic medications prescribed but not currently labelled for use in animals, little research has been conducted in veterinary medicine on the efficacy, safety and therapeutic benefit of alternative medicines in general. Research and education are warranted because, along with behavioural modification, they may offer an alternative or complement to conventional medicine, particularly if the latter is unsuccessful; however, until their efficacy can be quantified, their value relative to other interventions remains unknown.

Traditional Chinese medicine and acupuncture

According to the Western perception, TCM refers mainly to acupuncture. In fact, acupuncture is only a small part of Chinese medicine: the main part is clinical diagnostics and herbal medicine. TCM has a systematic approach to diagnosis and treatment and is a medical system in its own right. The temptation to understand TCM by fitting it into Western models is strong; however, reconciling both models is made

P.409

difficult because terminology used in TCM is not directly translatable to Western medicine. For example, a blood deficiency is not anaemia per se, but a pattern recognition of poor hair and skin condition, disturbed dreams and sleep, weak pulse and pale tongue. Energy in Western medicine has a different meaning from energy, referred to as *qi*, in TCM, the former measurable, the latter esoteric. The spleen in TCM is recognized as a major organ for transforming food into *qi* energy, where this function does not exist in Western medicine.

TCM recognizes pathology as arising from complex interrelationships between organs and organ systems. An animal's behaviour can direct us to an underlying pathophysiology and thereby to treatment. For example, phobias and **anxiety** are considered to be a disturbance of *shen* or **consciousness**, and can be caused by a 'blood deficiency', '*qi* deficiency' or 'heart fire'. In veterinary medicine, acupuncture and Chinese herbs are used to treat not only physical problems but also behavioural problems. For example, *dan shen* (*Salvia miltiorrhiza*) and jujube (*Ziziphus jujube*) are used to 'nourish the heart and calm the spirit'. *Dan shen* contains compounds that bind to the same sites as **benzodiazepines** on the **GABA** receptor complex, and is orally active as a tranquillizer in animals. Jujube contains saponins and flavones that have demonstrated sedative and anxiolytic activity *in vivo*. Acupuncture has been demonstrated to affect **endorphin**, **enkephalin** and **catecholamine** release, to inhibit sympathetic activation during mental **stress** and to invoke **analgesia** in animals.

Homeopathy

Homeopathic preparations are manufactured from specific plant, animal or mineral parts according to pharmacopoeia standards, where they undergo a series of dilutions and processing. These preparations are extremely dilute and, while their proposed mechanism of action is considered controversial, they are widely used by veterinary homeopaths. There are two fundamental tenets of homeopathy. The first is the principle of 'similars', which states that a patient's symptoms can be cured by a drug that produces the same symptoms of the ailment in a healthy individual. Homeopathic preparations have been theorized to stimulate recovery in a similar way to physical vaccines. The second principle is the repeated dilutions of a remedy, called the principle of 'potencies'. Despite multiple dilutions, the remedies are supposed to retain their biological activity.

A prescription is based on a diagnostic approach called repertorization. This means taking the case and matching symptoms of the patient to the remedy's toxic effects or known effects when used undiluted - hence the action 'like cures like'. Research is contradictory, with the placebo effect thought to explain the efficacy of homeopathy in some cases. The therapeutic value of homeopathic preparations in veterinary medicine remains largely anecdotal. For example, **fear** in animals is treated with a remedy selected on the 'totality' of symptoms and history. The more unusual or peculiar the symptoms, the more specifically a remedy can be selected. Remedies that are often selected for 'fear' include phosphorus, aconitum, belladonna, rhododendron, gelsemium or natrum mur. Reported success in the treatment of long-standing problems by trained veterinary homeopaths suggests that traditional scientific methods might be used to assess the validity of the therapeutic properties of homeopathic remedies.

Herbal medicine (phytotherapy)

‘Nervines’ are herbs traditionally used for ‘nervous’ complaints in people. Frequently, the traditional use of a herb is supported by scientific research, as biomedical actions are understood. Herbs have similar effects to conventional medicines and lend themselves well to clinical research. Notwithstanding the issues of variable potency of different plant crops and parts, and quality of manufactured herbs, the patient is treated according to herbal principles based on the phytotherapeutic principles of actions. Nervines may be sedating, activating or balancing and are traditionally used in formulas that take into account the whole patient symptoms, not just the diagnosis.

From a modern phytotherapeutic perspective *Valeriana officinalis*, *Ginkgo biloba*, *Piper methysticum*, *Hypericum perforatum*, *Passiflora incarnata* and *Matricaria chamomilla* are used for conditions ranging from anxiety and **depression** to **sleep** disorders. Like conventional medicines, herbal remedies have contraindications: some adverse events and drug interactions have been reported, so these medicines should be applied only with appropriate knowledge and caution.

T touch

Tellington touch, or T touch, is a ‘body work’ method based on circular movements of the fingers and hands on the body. It was developed originally for behavioural modification and training of **horses**, but has now been applied in **companion animals**, horses and in human nursing. Statistically and clinically significant differences in T touch groups have been reported in the literature for both humans and horses.

Flower essences

Bach Flower Essences® and numerous other flower essences (derived from imparting the essences of particular flowers in water) are readily available and very popular for the treatment of animals with a variety of behavioural problems ranging from stress, fear, anxiety and **aggression** to grief. Rescue Remedy® is claimed to be a ‘natural reliever of everyday stress’ in the company literature. An unpublished study (Cram, 2004) assessed the effect of two flower essences on intense environmental stimulation in people. Using a placebo control group design, the two flower essences were reported to reduce physiological activation and stress in subjects. There are claims for flower essences to ‘strengthen emotional equilibrium and equanimity in the face of stresses and environmental impacts’, thus reducing the typical ‘fight or flight’ stress response.

Nutraceuticals

Nutraceuticals are nutritional elements that can be used in a therapeutic way for the treatment of particular conditions. For example, phosphatidylserine, acetyl L carnitine and antioxidants may be useful in **cognitive dysfunction**. The use of melatonin to improve sleep and some cognitive measures in people has been studied, and it may also be useful in animals with cognitive dysfunction and obsessive-compulsive disorders and, possibly, thunder phobia in dogs. Melatonin may alter serum

P.410

sex hormone concentrations in male and female dogs. Female dogs treated with melatonin have been reported to exhibit significant decreases in serum oestradiol, **testosterone** and DHEAS (dehydroepiandrosterone) concentrations, and male dogs showed significant decreases in serum oestradiol and 17-HP (17-hydroxyprogesterone) concentrations. Melatonin may therefore have a role in **sexual behaviour** problems associated with hyperoestrogenism. An increasing number of nutraceuticals are available for treatment, or as an aid in the treatment of a range of physical and psychological conditions in animals.

Memory

Memory is the ability to store, retain and retrieve learned information over time. Without this ability to remember information, learning could not take place because, in the absence of memory, each encounter with the same **stimulus** would be perceived as novel. Similarly, without learning there would be no information available to be remembered - this demonstrates the closeness of the link between learning and memory. Memory, even its simplest form, is therefore necessary to allow animals, both wild and captive, to learn from their experiences, whether this concerns the spatial position of a recently located food source, reacquaintance with a previously familiar **conspecific**, the location of a preferred nestbox, the correct way to use an automated food dispenser successfully or **habituation** to the presence of a **stockperson**.

There are two main types of memory store: short-term (working) memory (STM) and long-term (reference) memory (LTM). In non-human animal memory research, STM tends to refer to temporarily stored information that lasts for seconds/minutes and is of limited capacity. In contrast, LTM refers to the ability to store information for a greater duration and has a huge capacity. LTM can be subdivided between explicit (declarative) and implicit (non-declarative/procedural) memory, with explicit memory being further subdivided between semantic and episodic memory. Explicit memory is a memory for facts and events (i.e. knowing that ...); semantic memory is the memory for facts and general knowledge, whereas episodic memory is the memory for specific events - knowledge that is connected to a particular time or place. Episodic memory therefore implies some degree of **self-awareness** that has been thought to restrict it to humans. However, recent research has suggested that some animals may be capable of demonstrating episodic-like memory, with scrub jays (a food-storing bird) appearing to remember what food they have stored, where and when. Implicit memory is memory for skills and habits (i.e. knowing how ...), and is often used to describe the memory processes behind simple learning phenomena such as habituation and associative learning.

The first stage of memory formation is acquisition - the process by which newly learned information (environmental input) is converted or encoded into a memory trace in the STM. The cellular mechanism thought to underlie STM involves the temporary facilitation of synaptic transmission between **neuron(e)s** in the **central nervous system** via increased neurotransmitter release. Some, but not all, memory traces may then undergo the second stage of memory formation, consolidation. This process incorporates both the storage and the retention of the memory trace in the LTM via rehearsal. In contrast to STM, the cellular mechanism thought to underlie consolidation to LTM involves the formation of structural changes to neurons (e.g. growth of additional synaptic connections) via protein synthesis. However, just because a memory trace has been consolidated does not mean that it will be retained or remain accessible indefinitely. The final memory

process is retrieval - the way in which individuals can actually refer to stored memory traces. This applies specifically to the retrieval of memory traces from the LTM back into the STM.

The flow of information through memory is thus as follows: an animal perceives environmental input via its sensory organs (e.g. visual, olfactory, auditory, etc.). This information is encoded in the STM and can influence response output (i.e. behaviour) directly or, following consolidation strategies such as rehearsal, can be stored and retained in the LTM. It is important to emphasize that the STM does not only hold new memory traces, but also those memory traces retrieved from the LTM. This is why the term 'working' memory is a useful description of short-term memory, because the short-term memory store is where the 'work' takes place, and where the information directing the response output is controlled.

None the less, not all that is perceived ends up in memory. **Attention** plays a critical role in filtering out the information that is 'unnecessary', so that only 'necessary' information is encoded into a memory trace in the STM. Only the information that catches attention is first attended to, then perceived and encoded - and only a fraction of this information is then consolidated for future reference. Some may be insufficiently rehearsed, others may not have the appropriate conditions for memory (see below). Even those memories stored, retained and retrieved from the LTM may not necessarily go on to influence response output, because motivation plays a key role in controlling response output. For instance, pigs may ignore the presence of a stockperson after

P.411

feeding time, but this is unlikely to be the case before feeding when they are hungry.

In humans we can assess memory by testing either **recognition** or recall of information. Recognition, for example 'Do you recognize this individual?', implies a verification of perceivable (present) facts. Whereas recall, for example 'Do you recall what a particular individual looks like?', implies a generation of non-perceivable (absent) facts. As a result, performance in recognition tasks is usually better, because of the presence of retrieval cues. When assessing animal memory, the majority of tasks used are tests of recognition - this is because recognition tests are easier to test non-verbally. Without verbal language it would be difficult for an animal to 'answer' a question such as 'What do you remember?' (a test of recall). In contrast, by displaying a behavioural change in response towards meeting something for the first time and then subsequent encounters, animals can non-verbally 'answer' questions such as 'Do you remember this?' (a test of recognition). Some of the recognition tests most frequently used to assess animal memory include habituation tests, delayed response tasks, the radial arm maze and discrimination training.

Before discussing some of these tests in more detail, it is important to emphasize that in memory research we must be particularly cautious in the interpretation of such memory assessments. While interpretations involving memory may adequately explain test results, it is vitally important to also consider other more parsimonious, non-memory, explanations for such results, e.g. **motivation**, satiation and error, before we move on to more complex explanations involving memory.

Habituation tests involve exposing an animal to a novel stimulus (e.g. a noise), upon which the animal shows a large response (e.g. ears pricking). If the same stimulus is then reintroduced after a subsequent time interval and the animal shows a decreased response to it, then this suggests habituation, and thus memory for the stimulus retained over that specific time interval. If, however, upon the reintroduction of the stimulus the animal shows no such decrease in the level of response (no habituation), then this may suggest memory failure. However, as mentioned previously, before we accept a memory interpretation of these results we should ensure that we have discounted alternative, non-memory explanations. For example, animals habituate only to functionally irrelevant signals - animals should never habituate to the sudden appearance of predator - so lack of habituation could also mean that the stimulus was salient on every exposure.

Habituation tests can be used to assess STM, e.g. seconds/minutes, but they can also be used to assess LTM. For instance, some species of migratory birds have been shown to recognize the songs of previously familiar conspecifics after 8 months of separation. Habituation tests are popular because they rely on a spontaneous 'natural' untrained response and, as a consequence, they are simple and often quick to use when compared with some other techniques. However, this is also a disadvantage in that any fluctuation in motivation may significantly affect performance, and so habituation tests are only effective for events that evoke a well-defined response.

Delayed response tasks are tests in which a delay, the 'retention interval', is interposed between a stimulus and the opportunity for a subject to respond to it. By altering the duration of the retention interval we can assess the duration of memory for the stimulus. Common examples of delayed response tasks are the delayed matching to sample test (DMTS), in which animals are rewarded for choosing matching stimuli, and the delayed non-matching to sample test (DNMTS), in which animals are rewarded for choosing non-matching stimuli. These tests are usually conducted using operant training procedures. The animal is initially shown a single stimulus on a screen, which it must peck/press to indicate that it is paying attention. Once pecked/pressed, this original stimulus disappears and there is a retention interval of several

seconds/minutes. Following the retention interval, two other stimuli are presented simultaneously, and the animal is rewarded for pecking/pressing either the one that matches (DMTS) or the one that does not match (DNMTS) the original stimulus.

Delayed response tasks deal only with STM, with accuracy (the proportion of correct to incorrect choices) falling rapidly as the retention interval is increased from just a few seconds to 1 or 2 min. The difficulty of remembering this type of information over longer periods is thought to be due to both the limited time between the different trials and the sheer number of trials received each day (often 100 trials per day).

Again we need to account and control for other possible factors influencing behaviour besides memory itself. For example, the experimental design should ensure that the stimuli are presented randomly on both sides of the screen, so that the task cannot be solved purely by responding to stimulus position. The benefits of this type of test include the amount of control the researcher has, and the increased attention and motivation to complete the task present due to reinforcement. However, because it requires training, it can be laborious for both the subject and the researcher. It can also be thought of as 'unnatural', given that there is frequently little ecological relevance for the subject. Although the experimental subjects in DMTS tasks are most commonly pigeons and primates, dolphins have also been used, and a spatial version of the DMTS task has been devised and used successfully in dogs to investigate the impact of **ageing** on memory performance.

The radial arm maze typically consists of eight identical arms radiating from a central area. The ends of the arms can be baited with small amounts of food, such that a hungry animal introduced into the maze will visit each arm and eat all the food. A typical test will involve introducing the animal into the central area of the maze with four of the eight arms closed (a 'forced' trial), so that the animal can only enter and clear the four open arms of food. It is then removed from the maze for a retention interval of a specific duration, and then reintroduced into the central area of the maze that now has all eight arms open. Animals can be trained either to return back to the same four arms, now re-baited, that it previously visited (a 'winstay' approach), or to visit the four previously closed arms (a 'win-shift' approach). Making errors (entry to 'wrong' arms) suggests memory failure over the retention interval, whereas making few errors suggests successful spatial memory for food/arm location.

Provided that we have adequately controlled for extraneous non-memory factors such as olfactory trails or search 'rules', we find that animals such as pigs can successfully learn to either 'win-stay' or 'win-shift' following retention intervals of at least

P.412

10 min. This suggests that the radial arm maze can be used for assessing both STM and LTM. While it does require training, this type of spatial memory test benefits from the fact that it is relatively 'natural' due to its use of **foraging behaviour**, and the animal is also well motivated to perform the task.

Discrimination training traditionally refers to procedures in which animals are reinforced for performing different, arbitrary responses to each of two or more stimuli, and is generally best used for assessing LTM. For instance, a pigeon can be trained to peck a disc to gain a reward when presented with one stimulus, but to refrain from pecking the disc and gain a reward when presented with a different stimulus. Once the pigeon has reached a specified level of accuracy during training, the training is stopped and a retention interval (e.g. days/months/years) begins. Following this retention interval the pigeon can then be retested; if it performs the discrimination at a level of accuracy above that expected by chance (even if the level of performance, as might be expected, has dropped since its initial training), then this suggests that the pigeon has retained a memory for that discrimination over the duration of the retention interval. Discrimination training can inform us about both the capacity and the duration of LTM - pigeons can remember several hundred images for a retention interval of several years.

The advantages and disadvantages of this type of test are very similar to those of the delayed response tasks (see above); however, unlike delayed response tasks, where the overall technique takes a long time to train but the individual trials themselves require no training, discrimination training requires the often arduous process of training an animal to respond in a particular way to each specific stimulus. When the time taken to train the subject is combined with the length of the retention interval and subsequent retesting, it can be a very long process.

Why is some information remembered for longer, and other information forgotten faster, than others? What are the conditions that influence memory during the three different memory processes? First, if we look at how memory can be improved, it appears that the more distinct, 'valued', emotionally loaded, long-lasting or frequent an event, then the better it is remembered. During acquisition there is a clear effect on subsequent performance of changing the duration of exposure to the to-be-remembered information. As presentation time is increased, so the memory improves - perhaps because it allows for more complete encoding. A similar effect occurs if, rather than increasing the duration of a single

exposure to information, you can expose an animal to repeated presentations of the same information - especially the greater the length of the first exposure and the shorter the gap between the presentations. This process is known as retroactive facilitation.

When a particularly surprising and/or distinctive item appears in a sequence of information, then it is remembered especially well. This is known as the von Restorff effect. For instance, if pigeons are trained to recognize a sequence of colours and a symbol is positioned within that sequence of colours, it is remembered better than if that same symbol had appeared in a sequence consisting only of other symbols. More information can also be remembered if it is 'chunked', that is arranged into meaningful blocks of information, rather than memorized as single units, although there is still a limit to the number of chunks that can be remembered. For example, pigeons learn faster if the training of colour and pattern matching is chunked by the experimenter. Events that are emotionally loaded may be prioritized in memory storage when compared with emotionally 'neutral' events, and the relative 'value' of the information to be learned may also affect its memorability.

For example, information about an **aversive** experience such as being placed in a weigh crate, the location of a preferred food or the identity of key social companions may be more memorable than emotionally 'neutral' events or less valued information. In one study, sheep required differing amounts of encouragement to run down a **raceway** according to the aversiveness of the event that they had previously experienced at the end of the race, either no handling (no encouragement needed), restraint (some encouragement) or simulated shearing (lots of encouragement). This suggests that the sheep retained information about the experience they had, and adjusted their behaviour according to how aversive they remembered it to be.

Memories, nevertheless, can be forgotten (either temporarily or permanently) as well as improved. Memory can be disrupted if there is interference during the consolidation process. If this interference occurs prior to the presentation of the to-be-remembered stimulus, it is known as proactive interference and, if it occurs after the presentation of the to-be-remembered stimulus, it is known as retroactive interference. This active disruption of memory consolidation by both proactive and retroactive interference results in permanent loss of a memory trace, and is one way in which memories can be forgotten. Examples of potential causes of interference include elements of common husbandry procedures, such as moving animals to a new cage, **handling** or introducing a novel conspecific. Such procedures may act as stressors, and high **stress** levels have been shown to disrupt memory consolidation. But memory consolidation can also be disrupted by non-stressful procedures, either because they shift attention away from the to-be-remembered information or, if the procedure includes information that is very similar to the previously learned information, by replacing it.

Such examples of interference can also result, post-consolidation, in temporary inaccessibility of an existing memory (retrieval failure). High stress levels influence memory retrieval because context - both internal (e.g. state of arousal and/or motivation) and external (e.g. test chamber colour and/or smell) - plays an important role in determining which memories are retrieved. It is thought that the presence of contextual cues aids the retrieval of the appropriate memory from the LTM. The absence of specific contextual cues may therefore lead to retrieval failure and thus apparent forgetting, even though the memory is still present and may only be temporarily inaccessible. Thus, forgetting can mean either temporary (e.g. retrieval failure) or permanent (e.g. disruption) loss of a memory trace. In addition to this 'active' process of forgetting, memory traces can also decay passively. This results in permanent forgetting, and occurs if there is insufficient rehearsal during consolidation to move the memory from the STM to the LTM. If there is insufficient space in the STM then a memory trace may be forgotten before it even has time to be consolidated.

P.413

Such apparent memory failure - even if only temporary - may lead to inappropriate behaviour being displayed and, in some situations, this may result in a reduction in **welfare**. For example, if, following a stressful handling procedure, a subordinate animal fails to display appropriate submissive behaviour towards a dominant individual that it encounters soon after handling due to (temporary or permanent) recognition failure, then this may result in the dominant animal becoming aggressive towards the subordinate - behaviour that might otherwise have been avoided. Care should also be taken to avoid exposing animals in **captivity** to cues that may result in the retrieval of negatively emotionally loaded memories, because such memories of negative events and their associated emotional state may result in a reduction in welfare - even in the absence of the actual aversive event itself.

Mentation

Mentation refers to mental activity; the process of thinking.

(PS)

Merkwelt

Derived from the German *merken* meaning 'to notice' and *welt* meaning 'world'. The merkwelt, as defined by Jacob Von Uexkiill (1934), is the perceptual world of the animal, which, along with the **wirkwelt** (i.e. the operational world), constitutes the animal's **umwelt**, that is, its subjective world. The merkwelt of an animal thus depends on its sensory abilities and is composed of all the stimuli the animal is able to perceive.

(SL)

Mesopredator

A mesopredator is a medium-sized predator, such as a domestic cat or fox. Mesopredators are of particular interest because their numbers in the wild will tend to increase when a larger predator is displaced from the environment (mesopredator release theory). As a result, there is increased **predation** of smaller prey species and less predation of larger ones, resulting in less **biodiversity** and potentially a major shift in the **ecology** of the environment as a result. For this reason, it is argued that it is important to conserve large top predators (e.g. wolves, etc.), since they suppress the numbers of mesopredators and so reduce predation of smaller prey species and increase biodiversity as a consequence.

(DSM)

Metacognition

Research on animal metacognition - **cognition** about cognition - is primarily concerned with the question: Do animals know when they know and when they do not know?

The study of animal metacognition is rooted in research on human cognitive psychology. The keys to human metacognition are beliefs and judgements about **memory**. For example, the question 'What is the name of the frog in *The Muppet Movie*?' might elicit a *feeling of knowing* - a judgement that one could select the name on a multiple choice test, even if one cannot recall it now. Such judgements, remarkably, can be made accurately even when the answer cannot be recalled. Metacognitive judgements are subject to some consistent biases, such as overconfidence, but they can also be quite accurate, especially when people can test themselves.

Animal cognition refers to animals' ability to process external information, store and retrieve that information from memory and produce resulting thoughts and behaviours. Animal cognition is often distinguished from other kinds of animal learning, such as classical conditioning and operant conditioning (**see: Conditioning - types of**). Different animals have different cognitive specialties; for example, many primates are social in ways that parallel human social **cognition**; some caching birds, for example, have spatial memories for the location of hidden food that far exceed those of humans.

The study of animal metacognition revolves around the concept of uncertainty - that is, discriminating between situations in which one is certain versus uncertain of what to do. Animals frequently appear to be uncertain - as when a horse

hesitates before jumping a hurdle that it may not be able to clear - but, by itself, appearing uncertain is not evidence of metacognition. The question that has been addressed over recent years is: Can animals report that they are uncertain? And can they report uncertainty about their memories?

Most of the evidence concerning animal metacognition is based on studies of rhesus macaque monkeys. Some of that evidence, as well as evidence from other species, is reviewed briefly below.

In seminal studies on animal metacognition performed in the mid-1990s, animals were given a task, such as identifying whether a tone was of high or low pitch. Crucially, they were also given a third response option, an 'escape' response, which allowed them to skip the trial and move on. Monkeys and dolphins both tended to escape difficult trials more than easy trials, providing the first evidence that they could make uncertain responses (see Smith and Washburn, 2005, for a review).

In another innovative study, rhesus monkeys were allowed to opt out of taking a test before it had occurred (Hampton, 2001). The subjects were shown an image on a touch-sensitive computer monitor; their task was to remember the image so that, later, they would be able to select it when it was presented along with other images in a multiple-choice test. The animals could also opt out of the test and settle for a food reward that, while less attractive than the reward for a correct response, was better than responding incorrectly and receiving no reward. The monkeys appeared to opt out of the most difficult trials, and thus they did better when they chose to take the test than when it was forced on them. This suggests they could monitor uncertainty in their memories. When pigeons were faced with the same task, however, they did not demonstrate an ability to monitor uncertainty.

A third kind of evidence for animal metacognition comes from a task in which, essentially, rhesus monkeys were asked to gamble on their memories (Kornell *et al.*, 2007). The monkeys

P.414

were shown six pictures, one at a time; they were then shown nine pictures and had to touch the one that had been presented previously. After they responded, the monkeys were asked how many 'tokens' they wanted to wager on their response. The tokens were icons, displayed on the screen, that were automatically exchanged for food rewards. If a subject touched the 'high risk' icon, they would either gain or lose three tokens, depending on whether their previous response had been right or wrong. If they touched the 'low risk' icon, they gained one token, regardless of their previous accuracy. The monkeys' bets demonstrated that they were confident following correct responses and uncertain following errors. More importantly, because the monkeys had previous experience with the betting paradigm, they were able to respond metacognitively beginning on their first day of the task. This finding implies that they had learned a general metacognitive ability that was not task-specific.

Self-reflection

Do animals experience metacognition the way humans do? In the study of animal behaviour, it is always critical to recognize that similar behaviours do not necessarily result from similar underlying processes and/or experiences. Many human metacognitive experiences, such as a tip of the tongue - when one feels tantalizingly close to recalling an answer (e.g. Kermit) that just will not come - are intensely conscious and involve an element of self-reflection. Thus far, the evidence suggests that some animals, including primates and dolphins, can distinguish between what they know and what they do not know. The degree to which they are aware of, or consciously processing, their metacognitive judgements remains uncertain.

Meyerson index

The Meyerson index is a laboratory measure of female sexual receptivity / **motivation** that scores the occurrence (or not) of lordosis in the female.

(DSM)

Microenvironment

The microenvironment is the environment immediately surrounding an animal, normally within a confined space in which the animal may live, e.g. inside a cage, or be temporarily placed, e.g. a **transport** vehicle, and, for the young, within a nest.

(DBM)

Milking

Milking is the removal of milk from the udders of lactating animals, most commonly dairy **cattle**, **goats** and **sheep**. Dairy cows of the *Bos taurus* species release their milk without the presence of their calf, but cows of the *Bos indicus* species usually need the psychological stimulus of the presence of the calf. The development of automatic machinery for milk extraction in the 20th century allowed many more animals to be milked by one herds person than previously, when cows were milked by hand. Milking units are now usually collected together into a milking parlour, where cows can be brought as a group and several animals can be milked at one time, under the supervision of a single herds person.

There is a wide variety of options for removal of the milk from cows, with the main considerations being the speed of throughput. Entry of cows into the parlour is often facilitated by the provision of a food reward at the same time as milking. The removal of milk in heavily lactating cows may offer reward in itself, and they are usually the first to enter the parlour if given the choice. Milking can be a stressful experience for cows if they are rapidly collected from pasture by a person with a dog or motorbike, if they are controlled in the collecting yard by an electric fence, if they are treated aggressively by the herds person in the collecting yard or parlour, if they are likely to slip on wet concrete floors or if they experience **pain** resulting from the slow removal of teat cups or an unsuitable vacuum level.

The best parlours allow the cow to enter her stall at will rather than being forced to enter by the herds person, such as autotandem parlours. Cows develop preferences to enter a specific stall at a specific time, and preventing them from doing this can increase their **heart rate** but it will not reduce their milk production. Recently, technology has been developed to enable teat cups to be automatically attached to cows, which has led to the commercial production of fully automated milking units, or milking robots. There are positive benefits to milking cows with robots - the vacuum and pulsation characteristics, which are standardized for all cows in conventional milking parlours, can potentially be tailored to the needs of individual cows in robotic milking systems. Inappropriate machine settings can be painful or induce haemorrhaging in the teats.

Stockpersons should have extra time to look after their cows if automatic milking units are employed, but are still required to fetch cows that do not want to be milked and to monitor milk storage and cooling. Robotic milking systems will increase the need for stockpeople to be better trained technically. An inadequate number can lead to long queues of cows, and cows may be reluctant to travel a long distance to be milked. Cows need to be trained and many are reluctant to be milked in

these systems, even if concentrate feeds are used to entice them. Also, a milking robot may not be able to adequately clean cows that come in from the fields in a muddy condition, leading to increased levels of **mastitis**.

P.415

Mind

The mind has puzzled people for centuries; both Plato and Aristotle, for example, presented theoretical accounts of it. Clearly, the mind cannot be literally observed under a microscope or dissected. It has long been known, however, that there is a close relationship between, on the one hand, mind and **brain** and, on the other, mind and behaviour. These relationships have given rise to two branches of science that come as close as we get to empirical study of the mind: *neuroscience* and *psychology*. Beyond this, a third field, the *philosophy of mind*, involves a priori investigation of the mental. Each field informs, and is informed by, the other two.

Psychologists investigate (among other things) mental development in children, sensation and **perception**, learning and **memory**, **emotion**, **personality**, thought and **language**, and various disorders and therapies. In neuroscience the main question about the mind is: How does the **central nervous system**, and particularly the brain, function to sustain mentality?

The philosophy of mind tackles a range of questions. First, what is distinctive about the mind? We know it differs from physical objects, but how exactly? One influential answer is that the mind involves **consciousness**. Secondly, what is the relationship between the mind and the body - and, more particularly, the brain? And given that mind and body are so very different, can we explain how bodily events cause mental events (burns hurt) and mental events cause bodily events (love leads you to the florist)? Thirdly, the mind is home to **knowledge**, beliefs and desires that represent things in the world. How does my belief that a cuckoo has arrived from Africa manage to represent, or be about, a bird species and continent? For example, I need not picture these things in order to have the belief. Fourthly, we all claim to know at least a little about the minds of others, but how can we know anything of the sort if all we ever observe is bodily stimuli (e.g. a punch) and behaviour (e.g. someone crying 'ouch!')? How do I know that you feel what I feel when you act as if you are in pain? This problem becomes more difficult when one turns from humans to other species (**see also: Anthropomorphism; Mentation**).

(PAR)

Miniature breed

Miniature breeds are distinguished by having a markedly smaller body size compared with other breeds. Miniature animals can be produced in two ways: selection for small size over consecutive generations, or utilization of one of many mutations for dwarfism.

The Lowline breed of **cattle** arose from a classic two-way selection experiment for yearling growth rate conducted in a population of Angus cattle by the New South Wales Department of Primary Industries, Australia. Fifteen years of selection for low growth rate resulted in a line with a mature body size 60% of the size of normal (control) cattle. When the experiment was completed, the existing animals from this line formed the foundation of the new breed. This is an excellent example of miniaturization as a result of recurrent selection. The miniature animals are proportionate, meaning that they have been equally miniaturized in all dimensions. It is likely that most of the differences in size among **dog** breeds arose from this type of selection.

Some dog and **cat** breeds exhibit disproportionate dwarfism, typically involving shortness of legs far in excess of what would be expected for their body size. Although the scientific evidence is very scant, it is likely that at least some of these breeds are reflecting homozygosity for a dwarfism mutation that has become a 'trademark' of the breed. If there are problems

associated with the dwarfism in such breeds, it may be possible to overcome these by outcrossing to another breed, followed by selection during subsequent backcrossing.

Dexter cattle are a miniature breed that originated in Ireland. Within this breed, a gene for disproportionate dwarfism is segregating. Homozygotes for the normal version of the gene are proportionate miniature animals known as long-legged Dexters; heterozygotes show disproportionate dwarfism (short-legged Dexters); and homozygotes for the mutation are grossly deformed **fetuses** (bulldog calves). In principle, the latter can be avoided by ensuring that every Dexter mating involves at least one long-legged Dexter. In practice, there is a substantial overlap in leg length between heterozygotes and homozygotes. A **DNA analysis** test is now available for distinguishing the two **genotypes**.

Mink

Mink are semi-aquatic mustelids that show adaptations for a hunting lifestyle on land and in water. Two species exist: the European mink (*Mustela lutreola*), which is rare or extinct in most of its original range; and the American mink (*Mustela vison*), which is native to North America and a resident alien in Europe. The American mink is used in the production of fur for the mink industry. Farming of mink originated in North America in the 1860s, but expanded to become a worldwide industry in the 20th century. As mink only breed once per year, they have experienced relatively few generations of selection in **captivity**. Therefore, while there has been some selection for production traits such as fur colour and ease of husbandry, the behavioural traits of farmed mink are little different from their wild counterparts. Indeed, farmed mink that have escaped or been released as a result of **animal rights** activism adapt rapidly to local environments and establish stable **feral** populations. American mink are considered a pest in European countries, and may be a serious threat to native wildlife, particularly for vulnerable species such as the water vole (*Arvicola amphibius*).

In common with wild mink, farmed mink mate in early spring and give birth to their young (kits) in early to mid-May. In the wild the young would be weaned between 8 and 11 weeks of age, with the faster-growing males usually weaned earlier than the females and leaving the natal territory. Farmed mink are normally weaned at about 5 weeks of age and then housed in male-female pairs (for ease of grading, as males are normally twice the weight of females) and fed *ad libitum* to **slaughter** at about 6 months of age. Farmed mink are traditionally fed a high-protein, high-fat diet usually made up of waste from the fish, meat, dairy and fur industries. After 6 months, those males and females kept for breeding are singly housed and fed a restricted ration to ensure that they are ideal weight for fertility in the spring.

Concerns for behavioural **welfare** of farmed mink centre on the incidence of apparently abnormal behavioural responses such as **tail biting** and locomotor **stereotypies**, and the

P.416

restriction of behaviours in conventional cages. Tail biting may occur in pairs or between mink housed in neighbouring cages, and it is believed this is a form of redirected hunting behaviour. Stereotypic activities such as **weaving** and somersaulting are rare in young, socially housed mink but normally develop during the winter period of feed restriction. Typically, these activities occur around feeding time and they may represent the perseverance of preprandial activities, coupled with conditioning due to predictable feeding regimes.

Restriction of behavioural **needs** in mink has centred on the value of swimming water. Mink are found to work as hard for access to swimming water as they would for food (**see: Economics of behaviour**), and to show elevated **corticosteroid** levels consistent with **distress** when prevented from swimming. This suggests that swimming water is a highly valued resource and essential for their well-being. The counter-argument is that mink need to have had experience of swimming in water before they develop a strong requirement to use it. As a consequence, farmed mink with no prior experience may not be deprived of the resource, whose value is context-specific as opposed to a universal need. This debate continues while, at a practical level, provision of water on commercial farms is being investigated.

The farming of mink for their fur has been banned in some countries (e.g. the UK), because of concerns regarding the welfare and **morality** of the trade. Despite continued campaigns by anti-fur organizations (e.g. Respect, PETA), worldwide production of mink fur has increased, with the largest industries in Denmark and China (about 25% of production each), while only about 10% of mink are still reared in North America, with the remainder in northern or eastern European nations.

(JC)

Mirror neuron(e)

Mirror **neuron(s)** are **brain** cells that become active when an animal both observes and undertakes equivalent actions, i.e. the observation mirrors the actual performance of a given behaviour. There is much speculation about their potential importance in a range of forms of **social learning** and **cognition**, although current direct evidence in support of these is lacking.

Mis-mothering

Mis-mothering describes a failure or deficit in **maternal behaviour** that places the offspring at increased risk of **suffering** and/or harm. Mis-mothering can occur as a result of endogenous or exogenous factors. For example, common reasons for mis-mothering include: (i) failure of the mother-offspring bond to occur (**see: Bonding - parent-offspring**); (ii) poor maternal skills due to a lack of experience or exposure during an important developmental period; (iii) delayed **lactation** (often as a result of hormonal disorganization arising from a prolonged, complicated or artificial, such as Caesarean section, birthing process); (iv) inhibition of **nursing** as a result of a painful **mastitis** condition, possibly induced by inappropriate suckling behaviour by the neonate; and (v) active rejection of sickly or weak individuals. In some cases young may be lost due to deficits in the offspring (e.g. weakness/illness), or accidents such as smothering or crushing by the mother when she lies down, and the loss of these offspring may be attributed to 'mis-mothering' in a broad sense, even though there is no deficit in maternal behaviour.

(DSM)

Mixed-species stocking

Many species are kept together in order to exploit resources more effectively. **Cattle** eat relatively long grass, scooping it into the mouth with the tongue, and this opens up a sward so that **sheep**, with their very selective biting action, can choose the highest-quality leaves and shoots. Generally, problems with **parasites** do not arise when the species are grazed together, at least in temperate climates.

In contrast, keeping donkeys and **horses** together can pose problems because donkeys can tolerate quite large infestations of lungworms without obvious symptoms. Horses are much less tolerant, so the donkey is effectively a reservoir of infection.

In African pastoral systems, **goats** are often kept in parallel with sheep or cattle. This enables households to spread risks, as goats can survive drought better than the other species.

There are other advantages to mixed-species stocking. A special case is the herding of sheep with cattle on ranches in the USA. If they have been imprinted upon each other when young, the cattle may defend the sheep from attacks by coyotes and other predators. Llamas have also been kept with sheep with the same intention.

Integrated systems with ducks, **chickens** and **pigs** being kept in pens above tanks of farmed fish are widespread in South-east Asia. Manure, urine and waste feed drop into the fish ponds, thus fertilizing algal growth, which is then eaten by herbivorous fish. This is highly efficient in terms of energy and nutrient cycles, but these systems have been implicated as a source of novel virus **diseases** that can threaten human life.

Mixed-species stocking enables resources to be used efficiently. There are disadvantages generally relating to human and animal **health**, especially when the systems are intensive, but substantial economic benefits are possible.

(SJGH)

Modal action patterns (MAP)

Modal action patterns (MAP) are relatively fixed, species-typical behavioural patterns that are performed in response to specific stimuli, similar to fixed action patterns (**FAP**). However, unlike FAP, MAP take into account variations both within

and between individuals in performance of the behaviour by referring to the most frequent measurement value (mode) shown in the distribution of the behaviour pattern.

(LMD)

Modality

The modality of a **stimulus** refers to both its physical properties and the medium through which it is communicated by another or transmitted. Stimulus modality is not a unique property of stimuli involved in **communication**, but also relates to stimuli within the physical environment, and so determines the perceptual world in which an animal exists (**see: Perception**).

(DSM)

P.417

Mollusc (mollusk) conservation and protection

Human-caused animal **extinctions** may be the ultimate of all human-animal interactions. Extinction is forever eliminating any other associations with humans. Since AD 1500, 643 animal species have been declared extinct, almost all from human activities such as **hunting** and harvesting, pollution and habitat degradation.

When we think of extinct animals, we tend to think of charismatic megafauna, passenger pigeons, dodo birds, Tasmanian tigers or Steller's sea cows. When we think of threatened or endangered species, we perhaps think of chimpanzees, gorillas, Siberian tigers, rhinoceroses, pandas, whooping cranes or California condors, each of which has campaigns and dedicated advocates devoted to saving them from that ultimate death. Yet 87% of all animal species are invertebrates, those animals without backbones. These are animals that are not necessarily cute and fuzzy and they have suffered the most sweeping extinctions.

Molluscs - notably freshwater snails and mussels - comprise 42% of the extinct animals today, more than all the extinct mammals and birds combined. In addition, 1930 non-marine molluscs are listed as threatened (only 41 marine species are so listed).

Freshwater mussels are particularly threatened. The south-eastern USA is the centre of diversity of the group, with over 300 species described from that area. Freshwater mussels were living in the streams there when the Appalachians were being formed, and are there now that the mountains have been extensively eroded. Endangered mussels with colourful names like purple wartyback, fluted kidneyshell, elktoe, orange nacre mucket and pink heelsplitter grow in their own particular stretches of the Tennessee and Mississippi River systems and, because of human activities, are losing the battle of survival.

First, Native Americans ate these mussels and they are well represented in ancient middens, the trash piles of the tribes. Secondly, European settlers discovered that these mussels made pearls inside themselves and countless millions were harvested solely for the pearl trade. Some mussel pearls were so highly valued that one was sold in 1902 for US\$65,000. Thirdly, mussel shells were used to make mother-of-pearl buttons in the early 1900s, and many more millions were harvested for this industry. At the peak of production, over 9700 harvesters collected mussels for this industry. Fourthly, 125 dams have been built since the 1920s on the waterways of the American South-east, isolating stocks of mussels behind dams, degrading their habitats with silt and slowing down river flows. Some 100-year-old mussels are isolated in between dams with no way to reproduce themselves, since the fish they need to disperse their young no longer live there.

They were again harvested, beginning in the 1970s, for seeds in the Japanese pearl oyster trade. A tiny piece of a freshwater mussel shell is placed inside the mantle of a pearl oyster, which the oyster then treats as an irritant. It lays down layers of nacre around the irritant to make it smoother, and the result is a cultivated pearl. Japanese pearl oysters recently suffered a 60% death rate due to a virus, dramatically cutting down the demand for freshwater mussel shells, and so helping their conservation.

In addition to the above threats to their existence and from the increasing pollution from human cohabitation, freshwater mussels are now facing another threat, from two of their relatives. The European zebra mussel was first found in the Great Lakes of North America in 1985, probably first arriving there in ships' ballast water, and has since spread dramatically into the Tennessee River. It is so prolific that it coats all substrates layers thick with its tiny shells, siphoning food from native bivalve species and smothering them to death. Another introduced invader from China, the tiny Corbicula clam, also competes for food in lakes and streams.

A few people are working at saving freshwater mussels by transplanting them to clean waters, raising them in laboratories, educating farmers not to fertilize fields close to rivers or to graze cows near streams where they could crush mussel shells with their hooves. Some efforts are being made to legislate protection of the threatened species, much like those used to save the Banff hot springs snail, which is only found in five hot springs near Calgary in Canada; three of the five are now protected, and snails have been successfully transplanted into hot springs where they had formerly been eradicated by human bathing activity.

But the future of many of the still-living freshwater mussels looks bleak. Unlike the millions of dollars donated for preserving condors, whooping cranes or pandas, little is generated for saving freshwater mussels or other threatened molluscs. When they become extinct, who will cry for the lost pink heelsplitters? Who will mourn what Lydeard and his colleagues called the 'silence of the clams'?

Monkey

Monkeys belong to the taxonomic order of primates; there are currently about 252 extant species of monkeys, in 461 taxa (see Groves, 2001). Primates are divided into two suborders, the strepsirrhines (consisting of the lorises and the lemurs) and the haplorrhines, which includes the tarsiers, monkeys and apes. The geographical distribution of monkeys is primarily restricted to the tropics: New World monkeys (NWM, platyrrhines) live in South and Central America and southern Mexico, and Old World monkeys (OWM) and apes (catarrhines) across Africa and Asia. Old and New World monkeys differ in several morphological features. NWM have nostrils that are wide open and far apart, while the nostrils of OWM are close together and comparatively narrow. Some NWM have a prehensile tail that can be used as an additional limb to grip; and some OWM, but no NWM, have ischial callosities, also known as sitting pads, on their backsides.

Most, but not all, monkeys differ from other mammals in several ways. They have forward-facing eyes allowing binocular vision, nails (as opposed to claws) on their fingers and toes, an opposable thumb to allow a pincer-like grip, a relatively large brain and a longer period of dependency of young. Some exceptions are the colobus monkeys, which do not have

P.418

thumbs (their name comes from the Greek word *kolobus* meaning 'cut short'), and marmosets and tamarins, which have claws on all digits except their big toes.

These features are adaptations to their lifestyles. The majority of monkeys are arboreal (tree dwelling), and they play a critical role in their tropical forest ecosystem as seed dispersers and pollinators. Other monkeys are ground dwelling and live on mountain plateaux (e.g. gelada baboons, which feed on grass), in deserts (e.g. hamadryas baboons) or savannahs (e.g. patas monkeys, which can run faster, at 55km/h, than any other primate). The geographical range of the Japanese macaque is further north and east than any other non-human primate; they have thick coats to endure the harsh, snowy winter conditions and some individuals sit up to their necks in naturally occurring hot springs to escape the freezing weather. All species of monkey are diurnal, with one exception, the aptly named night monkey (also known as the owl monkey) from South America.

There is considerable variation in the diet of monkeys. Understanding natural dietary adaptations and providing appetizing food with appropriate nutritional requirements is essential for good welfare. While fruit, leaves, flowers, seeds and other plant parts are eaten by most monkeys in the wild, many also eat gum and other plant exudates, insects, reptiles, birds and their eggs. Some monkeys are known to eat amphibians and crustaceans and are good swimmers (e.g. the crab-eating macaque, also known as the cynomolgus or long-tailed macaque). Others hunt and eat other mammals; for example, baboons have been known to hunt gazelle kids, capuchins eat baby squirrels and blue monkeys have been seen to eat another primate, the bush baby. Challenging the intelligence of primates to forage for their food in captivity may be critical for welfare and in preventing the development of abnormal behaviours. Capuchin monkeys use tools in the wild to

crack open nuts, but they are the only monkeys reported to use tools naturally in the wild (some other monkey species use tools under provisioned conditions and in captivity). Many primates will raid crops if their habitat is close to humans.

Monkeys vary greatly in size and weight; the smallest is the pygmy marmoset (adult head + body length is ~13.5 cm and they weigh 112-160 g), while the largest is the mandrill, with males measuring ~91 cm and weighing 27 kg - over twice the weight of females). Sexual dimorphism primarily depends upon the degree of competition among males for mates. In primarily monogamous species like marmosets, which rear their young cooperatively, males and females are similar in size. In polygynous mating systems, where males attempt to mate with several females (sometimes in harems), males are larger than females. One of the defining characteristics of monkeys is their social nature. All of the monkeys live in **groups**, ranging from small groups consisting of a mated pair and their immediate family to hordes of over 800 (in the case of mandrills in Gabon). There is a complex network of relationships within monkey groups - some cooperative and friendly and some competitive, as resources are scarce. The social bonds are often strengthened by **grooming**, and the enforced **dominance hierarchies** present in many species ensure individuals know their place. A series of ritualized threats minimizes the risks associated with physical fighting over resources. Grooming releases **endorphins** and appears to be pleasurable for the recipient. It is used as a 'currency' to trade for other desirable resources, such as mating. Understanding the natural social structure is critical for successful husbandry, to reduce the possibilities of fighting and in promoting affiliative relationships. Introducing unfamiliar individuals and forming new groups should be planned and managed carefully (see Jennings and Prescott, 2009) to avoid **injury** and prolonged **stress** or disturbance.

Monkeys have larger brains relative to body size than most other non-primate mammals. Their **intelligence** may have evolved to deal with challenges that they face in their social world, recognizing rank, friends and enemies, and responding appropriately to the behaviour of others. However, unlike apes, they are not able to take another individual's perspective, nor to deceive intentionally, nor do they recognize themselves in mirrors (they do not appear to have **self-awareness**).

The dominant sensory modality of monkeys is vision; they have both high visual acuity (i.e. ability to distinguish between closely spaced visual stimuli) and binocular vision. Many species of monkeys have elaborate pelage - manes, crests, moustaches, etc. - and often use their high-contrast markings in threat displays. All OWM, but only some NWP, have trichromatic colour vision similar to our own, which is important for selecting ripe fruits from unripe and semi-ripe ones, and may also confer advantages in detecting insect prey and predators. Colour vision also plays a role in **communication**; for example, during the mating season the facial and anogenital skin of rhesus macaques becomes redder and females prefer redder male faces over paler ones, possibly because it provides a cue as to the male's quality (Waith *et al.*, 2003). Most of the NWM are polymorphic in their colour vision; all males and some females are dichromatic (based on two classes of cone receptors, like humans with red-green 'colour blindness'), while some females are trichromatic. Dichromats have difficulties distinguishing yellows, greens, browns and reds, which may influence the design of behavioural experiments and the choice of colour cues for positive **reinforcement** training.

All monkeys have a well-developed sense of smell, which is important for food identification and selection, as well as in social behaviours. Many NWM possess odour-producing skin glands and demonstrate conspicuous marking behaviours; individuals use these olfactory cues to obtain social information such as individual identity, rank and reproductive status. Removing all scent from enclosures may be stressful and result in abnormally high levels of **scent marking**. Cleaning and sanitation of enclosures and **enrichment** devices alternately can help to retain familiarity. Monkeys can hear higher-frequency sounds than humans and have good low-frequency hearing. Noise (e.g. construction noise and ultrasonic frequencies) can have an adverse effect on welfare. **Vocalizations** are also an important mode of communication for monkeys and can be useful welfare indicators.

Assessing the welfare of captive monkeys should combine a range of measures. These include: (i) coat and body condition; (ii) physical values such as longevity, **growth rate**, fluctuations in body weight, susceptibility to **disease**, reproduction and infant care; (iii) clinical measurements, such as **heart rate**, blood pressure, body temperature, serum concentrations of various stress hormones - e.g. cortisol - and immunological

P.419

functions; and (iv) structured behavioural assessment. Behaviour is often the most accessible expression of welfare - monkeys that are well will appear relaxed (with **conspecifics** and in human presence), and spend much time grooming and foraging. Behavioural changes that may indicate poor welfare resulting from the present (or past) environment and/or experiences of the animal include a restricted behavioural repertoire, an abnormal **time budget**, inappropriate **social behaviour** and other abnormal behaviour patterns (Jennings and Prescott, 2009).

Non-human primates are used in biomedical research and in the production and testing of products and devices in laboratories. Ethical questions (**see: Ethics**) are raised due to their genetic proximity to humans, and the fact that they are

neurophysiologically highly developed. Their potential for suffering may be greater than that of other animals used in laboratories, because of the difficulties in providing an appropriate environment to meet their social, physical and psychological needs. The use of **great apes** (only the chimpanzee has been used in laboratory testing) has now been banned in many countries. Animal welfare and anti-**vivisection** organizations campaign to phase out the use of any non-human primates in laboratory tests and experiments. An estimated 100,000-200,000 primates are used in research worldwide (Carlsson *et al.*, 2004). In Europe around 10,000 monkeys are currently used in regulated procedures each year, approximately 0.1% of the total number of all animals used.

Worldwide, monkeys are used in the study of microbiology (including HIV/AIDS), neuroscience (including Parkinson's, Alzheimer's), biochemistry and pharmacology/physiology. In Europe the majority of monkeys used are in toxicity tests (safety and efficacy tests) during the development of new medicines. The most frequently used OWM are macaques (the cynomolgus and rhesus macaque), but other OWM used include baboons and vervet monkeys (also known as green monkeys). The common marmoset is the most frequently used NWM, but tamarins, squirrel monkeys and night monkeys are also used. Strict legislation surrounds their use in most countries. The use of wild-caught monkeys in laboratories is now banned in the UK, except under exceptional cases, and the rest of Europe may follow suit.

The housing and husbandry of monkeys in laboratories has improved in many countries since the late 1980s. In the best laboratories, cages are of sufficient size to permit monkeys to live in socially harmonious groups and to provide adequate enrichment to offer choice and control and to allow the monkeys to engage in species-specific behaviours and locomotion. Access to outdoor areas may also be given. In the worst laboratories, monkeys are housed singly in small, barren cages with little opportunity for social interaction. They are bored and fearful. They are often weaned too early and develop serious abnormal behaviours, such as **stereotypies** and self-injurious behaviours (**see: Self-mutilation**). Rennie and Buchanan-Smith (2006a,b,c) review refinements to primate use in laboratories (**see: Three Rs principle**). Positive reinforcement training (reward-based training) is a proven method of improving monkeys' perception of care staff, and may promote welfare as the monkeys learn to cooperate with many routine housing and husbandry events and, if required, in some experimental procedures such as venipuncture.

Monkeys are frequently kept in zoological collections; they are generally active, playful and inquisitive, making them popular with the visiting public (although, unfortunately, high visitor density may be a **stressor** for the monkeys if they are unable to retreat and hide). Many species are subject to **conservation** breeding programmes in **zoos** and private animal collections. In the wild, nearly half of all monkey species are threatened (in the vulnerable, endangered or critically endangered categories (IUCN, 2008)).

The threats they face are primarily from habitat destruction, **hunting** and pressure from the human population. This, combined with often small population sizes, means that many species are threatened with **extinction**. The rate of deforestation is much greater than regrowth, and encroachment by humans for farming brings monkeys and humans into close contact, and often into conflict if monkeys raid crops. Some **reintroduction** programmes, combined with conservation of forest fragments and reforestation to create corridors that connect them, have proved successful. There is a growing tourist trade to view monkeys in the wild and, while this may provide an incentive for locals to value and protect species, it has its associated problems. For example, monkeys that receive food from tourists lose their **fear**; they can become dangerous, and sometimes are shot as a means of control.

Hunting is mainly for food but, especially in Asia, also for traditional medicines, bait and body parts for ornamentation and amulets. People have hunted monkeys on a subsistence basis to feed their families for many years, but in recent years a market for monkey meat among the urban population has emerged. This **bushmeat** trade poses a very serious threat to the survival of many species. Eating monkeys is relatively common in Africa and Latin America, but is not so common in parts of Asia, where the religions of **Islam**, **Hinduism** and **Buddhism** forbid it. Monkeys are often caught in traps or shot. Live monkeys and fresh carcasses are sold at roadside stalls and in markets; the meat is often smoked to prevent it rotting. The fur of some species is prized - for example, the tails of colobus monkeys are used to make rugs.

In other areas humans worship monkeys, use them for assistance or keep them as **pets**. In India, the Hanuman langur is considered to be sacred by Hindus and will often be fed in temples. If a Hanuman langur dies before its time, Hindu worshippers may give the monkey a full funeral. In some parts of Malaysia, humans train macaques to help harvest fruit and nuts. Capuchin monkeys have been trained to assist severely disabled humans to perform basic tasks such as washing their face, combing their hair and microwaving food. Although some people keep monkeys as pets, a monkey's special needs can rarely be met, leading to health, psychological and behavioural problems and suffering.

Morality

Every society, cultural and social group tends to accept a number of beliefs about good and bad conduct (see: **Ethics**). A sense of values informs people's lives in terms of what they do, what they decide to do and their comments and judgements about themselves and others. People try, in various ways, to shape their lives according to moral values; they think that some kinds of life are more worth living than others, and have an outlook on life, and generally try to bring their children up to share this outlook. We might say that elementary beliefs about right and wrong are instilled into the young during the earliest stages of **language** acquisition and social interaction.

Language is impregnated with moral values and, at an early stage of social awareness, moral notions about justice and fairness, honesty and truthfulness will find expression; human children will utter moral judgements such as 'It is not fair', 'He is cheating/telling lies', and so on. Various rules requiring moral duties towards other beings may be taught by means

of analogy and appeals to self-interest. A parent or guardian might instil respect for sentient animals by confronting a child with the question 'How would you like it if someone hurt you, as you are obviously hurting the cat?'

With maturity and reflection, many elementary moral notions and the arguments supporting them can become increasingly sophisticated, showing an awareness of universal moral principles. During the course of one's life, ingrained values may be challenged and new moral principles and outlook may replace the old. This process, in many ways, resembles the development of science, where new circumstances challenge traditional and established beliefs, and new theories emerge to replace the old. An example of this process is the changing attitudes towards **laboratory, farmed and companion animals** since the mid- to late 1970s.

A popular, and largely correct, account of morality is that it is a means of restraining certain forms of conduct. Thus restrictions on cruelty and causing unnecessary **suffering** to animals are widely recognized moral constraints on behaviour. As a guide to conduct, morality can place constraints on both the ends and means of people's actions. Even if the end is universal happiness, morality may intervene, saying 'Not by this means'. An objective, like finding a cure for a **disease**, may be regarded as morally commendable, whereas the means might not be morally commendable if certain unnecessary and painful procedures are involved. From the moral standpoint, not only are the results of an activity to be assessed, but the procedures by which these results are achieved are also subject to scrutiny.

Although morality is sometimes described as a subjective or personal phenomenon, this is not strictly correct. There are moral principles that are universally acknowledged: in general, people disapprove of lying and cheating, and even more strongly disapprove of cruelty, causing suffering and seriously injuring or killing others. Exceptions may be allowed, but they are justified with reference to a higher moral priority: we may lie and cheat and harm others in order to defend ourselves or others from wrongfully inflicted harm or **death**.

The study of morality, and of the nature of moral argument, is called 'moral philosophy' or 'ethics'. For most purposes these terms can be used interchangeably, but they do have slightly different meanings. 'Ethical' is derived from the Greek word for 'personal character' and has a broader meaning, which includes concern with the value attributed to different kinds of lives and activities. The term 'morality', which is derived from the Latin term for 'social custom', is frequently restricted to its interest in rules and duties but it is often used when considering whether certain feelings or attitudes are of a moral kind. For example, 'remorse' (in response to, for example, a failure to carry out a particular duty) is considered to be a moral feeling, whereas 'regret' might not be. To experience remorse one must have made a moral judgement about one's action or inactions. The experience of regret need not involve any such judgement. A criminal may regret leaving his fingerprints at the scene of the crime, but this would not count as an experience of remorse. These considerations provide an insight into the nature of morality. It is a common, but nevertheless mistaken, belief that morality is reducible to **feelings** or **emotions**. It is not, although feelings and emotions may have a moral component. Consequently, it is not a sub-field of psychological enquiry.

Morality (and ethics) stands in contrast to other concerns. Self-interest may conflict with morality when an obligation to others is contrasted with selfish desires. In some respects a moral obligation may be contrasted with legal, political, economic and religious considerations. This does not mean that the latter are without moral content, but that the moral interest is different. From the moral standpoint it is always possible to question whether this law, political directive, economic reform or divine command is good.

This independent and critical feature of morality is nonreducible to other disciplines. Morality is a very powerful social phenomenon. Moral claims may conflict with self-interest, physical well-being and various forms of happiness. For this reason, it is mistaken to reduce morality to self-interest or even a set of rules that cement the social order. Theories of morality attributed to animals frequently display morality in this narrow

P.421

schema. It is sometimes held that animals in the wild exhibit various forms of moral behaviour. Studies of animal behaviour may very well corroborate this claim, but inferences drawn from the alleged social order of animal groups that carry the assumption that their moral system is functional in promoting social harmony will inevitably fail to depict morality. In contrast, pursuance of a moral imperative may result in selfdestruction or social disintegration. The 19th-century German philosopher G.W.F. Hegel notoriously drew attention to the fact that the great moral figures of history and literature, such as Socrates and Antigone, not only brought harm to themselves, but were very disruptive of the social order. The complexity of morality reflects the complexity of human social interaction. Whether or not non-human animals have a moral outlook is a controversial but, nevertheless, challenging avenue for research.

Morbidity

Morbidity refers to the incidence of **disease** or sickness (from the Latin *morbidus*, meaning 'sick'), and can be interpreted as the number of animals showing signs of disease at any one time (prevalence) or the rate at which animals become sick (incidence). It is used as an indicator of the level of infection. It can also be used as an indicator of animal welfare, as diseased animals commonly have poor welfare because disease can cause **pain, suffering, distress** and lasting harm. Some diseases cause poorer welfare than others, particularly those that affect bodily functions. For example, a disease that causes severe diarrhoea or pneumonia is likely to cause poorer welfare than those causing a slow-growing subcutaneous cyst or skin wart. The impact of a disease on an animal will directly affect its physiological well-being. It will also affect its psychological well-being if an animal is unable to carry out normal activities such as **grooming, playing** or **hunting** - that is, it may cause mental distress as well as physical impairment.

(DBM)

Morgan's Canon (Lloyd Morgan's Canon)

Morgan's Canon (1894) describes an application within the discipline of **psychology** of the scientific principle often referred to variously as the Law of Parsimony, the Principle of Parsimony ('seek the simplest explanation first'), Ockham's (or Occam's) Razor ('entities should not be multiplied unnecessarily'), in which it is stated that when there is more than one sound explanation for a phenomenon it is preferable to choose the simplest one.

Literally, the Canon states that 'In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the exercise of one which stands lower on the psychological scale'. This declaration was made in response to what Morgan saw as the anthropomorphic anecdotal approach to studying animal behaviour and the attribution of mental states to animals with regard to behaviours that might also be explained by simpler processes such as reflexes.

The Canon was used as one of the underpinning scientific principles fundamental to the development of **behaviourism**, although, contrary to the impression given in some texts, Lloyd Morgan himself appeared not to subscribe to a purely behaviourist school of thought, as he also states in the same text that 'The kitten has an impression of the ball with which it is playing, and the hungry dog may have an idea of a nice meaty bone', implying a belief in more complex cognitive concepts in these species. This highlights one of several problems with the application of the Canon, namely the level of evidence required before one should conclude that competing explanations are of equal merit. A further difficulty arises from the definition of a **hierarchy** of 'psychical faculties', since these may depend on the **behavioural ecology** and **phylogeny** of the species as well as its neuropsychological development.

Mortality

Mortality literally means 'able to die', but more commonly it means the death rate in relation to the population at risk, i.e. it is a frequency measure of **death**. The reasons why animals die are surprisingly few from a physiological viewpoint, although there are many indirect causes. The direct causes of death are cessation of the heart, leading to a lack of oxygenation of the heart and **brain**, or destruction in some way of the vital centres of the brain in the brain stem that control respiration and **heart rate**. In humans it can be more complex, as a person may have had the brain stem destroyed (i.e. be brain stem dead), but the vital functions of breathing and oxygenation are taken over, e.g. by a ventilator and

forced respiration. In such cases the mid- and forebrain may still function, but such treatment may become futile as there is no chance of recovery and so, at some point, the decision has to be made to stop such rescue 'treatment'.

(DBM)

Motivation

Motivation is the process within the **brain** controlling what behavioural changes occur and when. It can be thought of as the summing of various causal factors that contribute to an animal's decision making, resulting in it behaving in a particular way. These factors combine together and, based upon the animal's assessment of its total internal state by the brain, incorporation of likely future demands and of new demands to be created by any given course of action, the animal chooses what to do next.

Internal and external causal factors

In the process of decision making, an animal is likely to receive a wide number and variety of inputs. For example, consider an animal searching for food. A number of factors could influence how this behaviour is expressed. There might be sensory input to the brain from the external environment, e.g. when a potential food item is detected. There will be internal input from body monitors such as blood nutrient levels or gut distension. There could be internal input from oscillators within the body, producing an output after a particular time and indicating normal feeding time or interval since the last feed. Nevertheless, there are likely to be other factors involved in the motivation process. The animal might have an injury,

P.422

resulting in licking rather than food searching. There might be input about the presence of a potential mate or predator, which again leads to some other activity being given priority over food searching. Fluctuations in hormonal status will also change the likelihood of occurrence of various behaviours.

Each of the above factors will also be influenced by the animal's previous experience. For example, the smell of a food that the animal has experienced previously but found distasteful might reduce the probability of the animal initiating food searching or, the gut might be empty but experience shows that the gut has to be empty for several hours before food will arrive. Each input to the brain must be interpreted in relation to previous experience. Some inputs will never reach the decision-making centre in the brain because the interpretation results in their relevance being assessed as zero. The actual inputs to the decision-making centre, which are the interpretations of a wide variety of external changes and internal states of the body, are called causal factors.

Motivational state

The traditional view of motivation is that a change in the animal's internal state is sensed by the brain and leads to a build-up of drive to perform the appropriate behaviour. The drive gives rise to **appetitive** and **consummatory behaviour**. Appetitive behaviour involves searching for suitable external stimuli; when these are encountered consummatory activity, such as eating or drinking, occurs. The term '**drive**' was introduced as an alternative to the concept of instinct and was intended to distinguish between the energizing (drive) and the directing aspects of motivation, although for a range of reasons (e.g. see 'feed-forward' below), the concept has tended to be dropped over recent years. In the traditional view, behaviour was driven from within, and there is a direct causal relationship between the strength of drive and the properties of the ensuing behaviour.

In the modern view, the relationship between motivation and behaviour is not necessarily direct. Although particular combinations of factors can give rise to a given tendency, there is not necessarily a direct relationship between the tendency and the observed behaviour. For example, an animal might have a tendency to feed that is stronger than any other tendency but, in the interests of some long-term strategy, it may postpone feeding; or an animal may feed even though its feeding tendency is not the strongest tendency (e.g. as a **displacement behaviour**). This modern view has given rise to the concept of motivational state.

At any particular time the animal is in a specific physiological state, which is monitored by the brain. The behaviour that is expressed is determined by the brain as a result of monitoring these states, in combination with the animal's perception of environmental stimuli. The combined physiological and perceptual state, as represented in the brain, has been called the motivational state of the animal (McFarland, 1993, p. 306). It includes factors relevant to developing activities, as well as to the animal's current behaviour. It is thus fundamentally different from the old concept of drive that it has come to replace. The animal's motivational state can be represented by a point in a multidimensional motivational space. The

multiple axes of the space are the important motivational stimuli, such as the degree of thirst or the strength of some external stimulus. This state-space approach is useful in describing complex motivations that the more 'generalized drive' concept is not. For example, animals might not be simply hungry, they might be hungry for a particular food type. In the state-space approach, the x-, y- and z-axes might represent the strength of motivation for fat, protein and carbohydrate, respectively. Any point within the state-space will represent the animal's overall tendency to eat food of the particular type.

Models of motivation (Manning and Stamp-Dawkins, 1992)

Perhaps the most famous model of motivation is **Konrad Lorenz's** 'psychohydraulic' model. This draws an analogy between the way a water tank with a spring valve operates (e.g. immediately after flushing it cannot work until the water has had time to build up) and animal behaviour (e.g. immediately after feeding, it may be more difficult to elicit more feeding behaviour). This model was inspirational in its time, but is now considered to be unsatisfactory. For example, as long as the tank has not been recently emptied, it should be able to discharge water and should only cease to be able to do so when all its water has been used up. If animals operated in this way, they would stop behaving in certain ways only when their motivational equivalent of water has been used, i.e. through previous performance of behaviour.

However, there are a number of cases where behaviour ceases without the full sequence having been performed. For example, if food is placed directly into the stomach of a hungry dog, thus by-passing the act of eating, the dog does not eat nearly so much when subsequently offered food. It is the stimuli from the distended stomach, not the act of eating, that is the most important in switching off feeding behaviour. The major problem with Lorenz's 'psychohydraulic' model is that it does not incorporate a feedback function. Many behaviours such as **feeding**, drinking and nest building are affected by what the animal has done earlier, through the animal's own actions on its environment. These feedback effects have now been incorporated into a number of motivational models under the general heading of homeostatic models.

The body is constantly adjusting itself to cope with changes in the external environment. It maintains relative stability despite sometimes massive fluctuations in the outside world. This stability of the internal environment is termed **homeostasis**. The starting and stopping of behaviour can be seen as part of the homeostatic process. On a hot day, body fluids decrease; this stimulates the animal to drink, which helps to correct fluid loss, returning the body fluids to some 'ideal' or normal value. Homeostatic models assume that there is an ideal state or set point for the animal. If there is a difference between the set point, e.g. for body fluids, and the actual state of the animal, this difference is said to provide the motivation for drinking. This is described as a 'negative feedback' loop because error is 'fed back' into the system.

In many instances, negative feedback models of motivation seem to provide a good analogy to the behaviour of a real animal. Rats injected with salt, which dehydrates them, drink just enough water to restore their fluid balance. The effects of placing food directly into the stomach, which Lorenz's model does not explain, are also understandable as a homeostatic

P.423

model: loading the stomach with food is enough to 'turn off' eating, because a full stomach is normally part of the negative feedback loop of the homeostatic feeding system.

We should not think, however, of an animal's behaviour as being controlled by something analogous to a simple thermostat. Factors influencing motivation can be considerably more sophisticated. If humans are deprived of water and then allowed to drink, they will drink almost all that is needed to restore fluid balance within 2.5 min, although changes in plasma dilution cannot be detected for 7.5 min and are not back to normal for about 12.5 min. Studies have shown that water is detected in the mouth and throat during the course of normal drinking and reduces the subsequent tendency to drink. Distension of the stomach and stimulation of the intestine also play a part in terminating drinking. The exact stimuli influencing even the same behaviour differ between species. For example, in dogs gastric distension is relatively unimportant for drinking, but it is very important in monkeys. Drinking can also occur because of an anticipated fluid deficit. When given dry food that makes them thirsty, rats will drink in anticipation of this, a phenomenon called 'feed-forward'.

Animals use a variety of cues and previous experience to predict that an internal state will depart from the tolerable range, and they behave in a way that prevents this from happening. When feed-forward control is very efficient, an observer may be unaware that any change in state would have occurred, because the action compensates for it exactly.

Simple homeostatic models cannot explain all aspects of behaviour. Animals fed to satiety on one type of food will often resume feeding if given a wider range of foods. Under experimental conditions this can be so excessive that animals will eat until they are grossly obese.

It has been argued that there should be a distinction between behaviour that is homeostatic and behaviour that is not. This separates behaviours such as feeding and drinking, where there is an identifiable set point, and other behaviours such as **aggression** and sex, where it is difficult to see what the set point would be. Others have argued that there is not really a fundamental difference between the two categories, because all behaviour has consequences for the internal state of the animal performing it.

Two behaviours that have been widely studied and that have allowed us to develop understanding about causal factors are **dust bathing** by chickens and nest building by sows. If hens are allowed free access to a suitable substrate, they will dust bathe with a clear **diurnal rhythm** approximately once every 2 days. If they are deprived of a suitable substrate, the intensity of dust bathing is greater when access is reinstated (**see: Rebound behaviour**), suggesting that there is an increase in the motivation to perform dust bathing and therefore an influence of internal causal factors. In addition, hens will explore more in the absence of dust-bathing substrate, and can learn an association between a colour cue and a suitable substrate, both indicating that chickens can be motivated to perform dust bathing in the absence of substrate.

External causal factors also affect dust bathing. Chickens provided with a finely structured substrate, such as peat or sand, perform more dust bathing than if they are provided with, for example, wood shavings or feathers, although experience can influence preferences. Heat, light and the sight of other hens performing dust bathing are other external factors that can increase the probability of dust bathing occurring. One model of dust bathing behaviour is that internal factors build up with time since the previous performance, whereas the **circadian rhythm** sets the threshold for the behaviour to be initiated. External factors (heat, light, **social facilitation** and substrate) affect only the threshold.

An alternative model based on the theory that behaviours are regulated through motivational affective states is more consistent with an 'opportunity' model. This predicts that, given the opportunity, hens will dust bathe and feel pleasure from doing so but, in the absence of external stimuli, dust bathing motivation will be low. The reality probably lies somewhere between the two models, and the relevance of the internal and external factors, respectively, may reflect an individual's situation in that specific moment in time (Olsson and Keeling, 2005).

Measuring motivation

It is important to measure motivation for two reasons. First, motivations for different behaviours often interact with each other. If we are to understand these interactions and attempt to predict when a particular behaviour might occur, we need to measure not just the strength of its own causal factors, but also the relative strengths of the motivations for other behaviours. Secondly, measuring motivation can have a practical application. Many people are concerned that the **housing** and husbandry systems we have for **captive animals** deprive them of performing much of the behaviour they would be able to do in the wild. If we can measure the strength of motivation to perform the behaviours the animal is 'deprived' of, we might be better able to understand the **welfare** implications. It is usually impossible to directly measure the internal state of an animal, but we can measure responses that are indicative of this.

Amount of activity performed

A straightforward way of measuring motivation is to give the animal the opportunity to perform a response and record how much or for how long the behaviour is performed. We can record the number of drinking movements or, alternatively, record the amount of water drunk by the animal. We can measure the motivation for dust bathing by recording the length of dust bathing or the number of dust-bathing bouts. This can be recorded at various times of the day to measure rhythmicity of motivation, or after periods of deprivation. Many complex behaviours, when they have not been elicited for some time, have a lower threshold and are performed at a high intensity when they are finally elicited. This is sometimes called 'rebound behaviour'.

Aversiveness of stimuli

If we attempt to prevent the animal from performing a behaviour, we can measure how much the animal will persist despite this. One example would be to taint food or water so that it tastes unpleasant. The concentration of the taint can be gradually increased until the animal eats or drinks less, or stops altogether, thereby measuring the motivation to eat or drink. A variation on this is to place an aversive obstacle

between the animal and an aspect of the environment with which the animal is motivated to interact. This obstacle might be a traverse of water, an electric grid, a blast of air, a narrow gap, etc.

Operant behaviour

Animals can be trained to press on bars, peck at keys, pull on chains, etc. to receive a reward or gain access to a section of environment that allows them to perform a particular behaviour. The animal does not usually receive the reward or gain access for each operation on the manipulandum (alterable characteristic), but might receive it after a pre-set or variable number of operations, or after a period of time has elapsed subsequent to the operation. The rate at which animals operate the manipulandum can be used as a measure of motivation. For example, under some **reinforcement** schedules (i.e. variable interval), the rate at which water-deprived rats will bar press is highly reliably related to the length of time that the animal has been deprived of water. Consumer demand studies (see: **Economics of behaviour**; **Elasticity of behaviour**) take this technique further by increasing the number of operations the animal must perform to receive the reward or gain access to the desired environment. The number of required operations is plotted against the number of reinforcements that the animal receives.

Vacuum activities and stereotypies

When animals are highly motivated to perform a behaviour, this behaviour is sometimes expressed even when the appropriate stimuli are not present. One example of this is dust bathing in hens. Hens kept in wire-floored cages sometimes perform all the movements of dust bathing, even though there is no substrate for them to dust bathe in. This has been termed vacuum or sham dust bathing. The term 'vacuum' is used to indicate that the behaviour is performed in the absence of suitable stimuli, or at least with minimal stimuli, and it suggests that the animal is highly motivated to perform the 'deprived' behaviour.

Many animals confined over periods of time can develop **stereotypies**. The presence, frequency and intensity of stereotypies in the behavioural repertoire of captive animals has been taken by many people to suggest that the animals are highly motivated to perform some behaviour they are unable to carry out in the confines of a cage, but the aetiology of stereotypies is complex.

In summary, there are several ways of measuring motivation. We might think that they are measuring the same aspect of behaviour and in a way that we might expect would change in the same way. However, studies measuring three aspects of feeding motivation show that this is not necessarily the case. In hungry rats, the amount of food eaten, the amount of quinine accepted and the rate of bar pressing do not all rise together. Over the range 0-54 h of food deprivation, the amount of quinine that rats will accept steadily rises, as does their rate of bar pressing, but their food intake reaches a maximum after only 30 h and actually declines slightly thereafter. Thus, a rat appears to be becoming 'hungrier' in that it will accept food that is increasingly bitter, and yet it eats less. 'Motivation' is a term that attempts to integrate a range of causal factors, including the animal's internal state (hormones, nervous inputs, etc.), external changes and previous experience, so it is hardly surprising that these various components do not always change in exactly the same way.

Motivational state

Motivation is the product of an assortment of stimuli involved in leading an animal to perform certain behaviour patterns towards a goal. An animal's motivational state determines the likelihood of an animal performing one behaviour pattern rather than another at any point in time. Motivational state is influenced by both internal factors, such as gut fill, and external factors, such as the sight of food, although the relative importance of internal and external factors varies between different types of motivated behaviour. The behaviour pattern with the strongest motivation is the one that the animal will direct the most time and effort towards trying to achieve.

Animals in **captivity** have surroundings quite different from their wild counterparts, which can be quite stressful and may only allow a limited number of behaviour patterns to be performed. The **frustration** or thwarting of strongly motivated behaviour patterns is **aversive** and can lead to behavioural changes and, ultimately, **stereotypies**. There is evidence for two types of motivational explanations for stereotypic behaviour: (i) that they derive from **redirected** or **vacuum behaviour** performed by frustrated or thwarted animals; and (ii) that they derive from escape attempts shown by frustrated or thwarted animals. To decrease the performance of such behaviour patterns, it is important to house animals in environments that allow them to fulfil the behaviour patterns that they are most strongly motivated to perform.

(LMD)

Mouse

Mouse is the common name that is generally, but imprecisely, applied to **rodents**, found throughout the world, with bodies less than approximately 12 cm long. In a scientific context, mouse refers to any of the 38 species in the genus *Mus*, which is the Latin word for mouse. The **welfare** of mice and range of actions deemed acceptable towards them vary enormously according to whether they are considered a **pet**, **laboratory animal** or pest species.

P.425

Mule

A mule is a cross between a male ass, *Equus asinus* (jack), and a female **horse**, *Equus caballus*. The much less common offspring of male *E. caballus* and female *E. asinus* (jenny) is called a hinny. Although genetically identical, these animals may differ in size at maturity as a result of maternal effects that include early nutrition and, to a lesser extent, uterine volume.

Mules have an appeal as working animals because they are generally larger than regular donkeys and so can haul heavier loads. Their donkey heritage means that they are more resistant to dehydration than horses. From a **welfare** perspective, this may mean that they are exposed to workloads that would overwhelm a horse of equivalent size, and the behavioural characteristic often labelled 'stoicism' - the absence of resistance - is a trait that may predispose the mule (and indeed donkeys) to abuse.

Although irregular, female mules commonly have **oestrus** cycles and often have follicles that ovulate and luteinize, but they generally lack oocytes. The degree of functional infertility in mules varies considerably (Zong and Fan, 1989) and, very occasionally, they even bear live foals (Ryder *et al.*, 1985).

The differences between the **ethograms** of donkeys and horses should be considered when **handling** and training donkeys and mules. For example, donkeys tend to have different responses to **fear**-inducing stimuli, tending to freeze more readily than horses (a distinct advantage if they become stuck in barbed wire). Other differences relate to the amount of training and human contact experienced by the individual - donkeys and mules have often been exposed to fewer controlled learning experiences than horses.

Hoof trimming is critical in many donkeys and their hybrids on good pasture, because their arid origins prepare them for substrates that abrade the solar surface of the hoof. In the absence of this sort of wear and tear, hooves can rapidly become overgrown to the extent that they disturb the hoofpastern axis and affect **gait**, thus compromising the animal's ability to move about. To compound the problem, many handlers find difficulty in administering pedicures since these

animals have tremendously good balance and are often reluctant to raise their limbs on demand. Early and sustained training to pick up the feet is therefore desirable.

Mulesing

Mulesing is the removal of flaps of skin around the hindquarters of a young **sheep**, particularly of the Merino breed, which can become soiled and predispose them to **fly strike**. It is a common practice in several parts of Australasia as a result of the prevalence of this breed in these areas. Although the consequence of the procedure is an effective deterrent, it is a cause for concern as it is undoubtedly painful and not normally undertaken with any form of **anaesthesia** or **analgesia**, nor necessarily antiseptic, and may be undertaken by trained non-veterinarians. It is being phased out under animal welfare legislation in many regions, but is maintained in others on the basis of a cost-benefit risk and financial analysis (**see: Ethics**). Some countries have also banned the import of wool from mulesed individuals as a result of **welfare** concerns arising from the practice.

(DSM)

Mutation

A mutation is a change in a segment of DNA. Many **mutations** result from mistakes in the replication of DNA. Some mistakes are quickly corrected by the cell, but those that are not are passed on to the cell's descendants. If a mutation occurs in a cell that forms sex cells (germ line mutation), it can be passed on to the next generation. If it occurs in other cells (somatic mutation), the stage of the animal's development when the mutation occurs will dictate how much the animal is affected.

The simplest type of mutation involves the substitution of one base for another. If this occurs within a coding region of a gene, it can change a functional codon to a stop codon (nonsense mutation), result in the substitution of one amino acid for another (mis-sense mutation) or, because of the redundancy in the genetic code, it can result in a different codon that still signifies the same amino acid (silent mutation). Insertions or deletions of other-than-three bases in a coding region, which result in a change in the reading frame, cause the ribosome to read a completely different set of codons downstream (frameshift mutation), and hence typically result in a non-functional peptide. Mutations occurring outside coding regions can also have adverse effects (e.g. if a mutation occurs at an exon-intron junction, it can 'derail' the splicing of introns, resulting in a very abnormal peptide).

If a mutation exerts its effect in heterozygotes, it is said to be dominant; if it has an effect only in homozygotes, it is said to be recessive.

It is very important to realize that mutations are natural phenomena, and, even though they occur very rarely (with a frequency of around one in a million), they have been occurring for so long that they are ubiquitous: almost every animal (even the purest of pedigreed animals) is carrying several lethal recessive mutations. It is, therefore, futile to think of eliminating all recessive mutations.

(JA, FWN)

Mutations

Behaviour

Normal behaviour is the result of the action of many physiological processes. Although knowledge of these processes is far from complete, it is evident that many peptides are involved in the regulation of these processes. Each peptide is encoded by a gene, and is under the control of other genes that determine when and where that peptide is transcribed and translated. A **mutation** in the encoding gene can result in an imperfect form of the peptide or the absence of the peptide; a mutation in any of the controlling genes can result in the peptide being produced at inappropriate times and/or places; or not being produced at all. As a consequence, one or more physiological processes may be disrupted. If a disrupted physiological process affects behaviour, then **abnormal** behaviour may result. Because the mutated gene may be passed

P.426

on from generation to generation, the resultant abnormal behaviour can also be inherited. In this way, mutations can give rise to inherited behavioural abnormalities.

Many such mutations have been documented in **laboratory animals**. For example, there are more than 100 behavioural mutants documented in the mouse; these have been given names such as Bronx waltzer, dancer, disoriented, dervish, Jackson circler, pirouette, pivoter, twirler and waddler. In non-laboratory animals, there are far fewer reports, reflecting lack of research rather than absence of mutations. This entry focuses on behavioural mutants that have been reported in non-laboratory animals.

Welfare

Most mutations are deleterious in the sense that they result in abnormal biochemical/physiological processes, which in turn can result in 'sickness', often leading to premature **death**. Hence, many mutations have adverse effects on **welfare**. However, mutations are natural phenomena and are very widespread; in fact, almost all animals (including the purest of pedigree animals) are carrying several recessive lethal mutations. Consequently, it is not realistic to aim to remove all deleterious mutations from a population, since the only way to do this is to eliminate the entire population. Fortunately, most mutations are rare, due largely to natural selection against them. When they appear in a family that comprises otherwise highly favoured animals, it is possible to eliminate recessive deleterious **phenotypes** from a population without eliminating the mutations themselves: all that is required is for each mating to involve at least one parent that is homozygous for the normal allele. Some typical examples of these types of inherited disorders are described later.

One particular type of welfare problem exists where a deleterious mutant is maintained in a population because of **selection** favouring heterozygotes for that mutation. In such cases, society at large has to decide whether, on balance, the advantages inherent in the heterozygote are sufficient to justify deliberate selection to maintain the deleterious mutation in the population. In the interests of animal welfare, breeders must be prepared to accept that their favourite mutation may have sufficiently severe welfare implications to warrant its elimination.

Behavioural mutation

One common mutation having a major effect on behaviour in animals involves roller and tumbler pigeons, which have been recognized (and bred) for many hundreds of years. Pigeons with this trait perform backward somersaults either in flight or on the ground, either once or twice (tumblers) or repeatedly (rollers). This behaviour is most frequent in parlour tumblers or rollers, in which any attempt to fly results in tumbling or rolling on the ground. Neither the gene nor the causative mutation has yet been identified.

Structural mutation

Munchkin cats

Munchkin **cats** are characterized by short legs. This shortleggedness is caused by a natural mutation that has been kept in the population by selective breeding for the short-legged phenotype, which is a form of disproportionate dwarfism (**see: Miniature breed**). The gene causing this phenotype appears to be an autosomal dominant, but reliable data have not yet been published. The short legs of these cats do not affect their climbing ability, but do seem to affect their ability to jump. The limited evidence available suggests that Munchkin cats are similar to Dachshund and Corgi **dogs** and, if this is confirmed, the welfare implications for Munchkins should be similar to those for short-legged dog breeds.

Twisty cats

Twisty cats have a phenotype characterized by radial hypoplasia: the forelimbs are severely crippled due to the absence of all or part of the long bone from elbow to wrist, leaving either no paws or only vestigial paws. Affected animals hop around

much like a kangaroo. Their powerful hind legs give them the ability to jump, but they struggle to land. Cats with this disorder develop sores on their legs and have problems with ingrown toenails. In the absence of published inheritance data, it is not possible to say whether this phenotype is the result of a mutation, but information from breeders suggests that it is.

Deleterious mutations maintained by selection and favouring heterozygotes

Scottish fold cats

Scottish fold cats are characterized by ears that fold forward. This phenotype is due to a dominant mutation that has been selectively bred into a population of cats. In the 1970s, it was recognized that homozygotes for the mutation show severe clinical signs of osteochondrodysplasia, reflecting abnormalities in cartilage maturation, and resulting in an abnormal **gait** that deteriorates until affected animals can no longer walk. More recently it has become evident that a large proportion of heterozygotes are also adversely affected, albeit less severely than homozygotes, but sufficiently to raise welfare concerns. The molecular basis of the mutation has not yet been discovered, but affected homozygotes can be avoided by ensuring that each mating involves at least one non-fold parent. Also, it should be possible to select against osteochondrodysplasia among the offspring of fold × non-fold matings.

Manx cats

The Manx cat is easily recognized because of its very short or absent tail, which is due to an autosomal-dominant mutation. The tailless phenotype is the heterozygous expression of the mutant gene, which causes disruptions in embryological development, preventing normal formation of the caudal neural tube. Tail length varies from slightly shortened (longie) to the complete lack of tail vertebrae (rumpy). Manx cats also show a range of anomalies of the lower vertebrae and anal region. Abnormal anal and perineal denervation has been shown to cause megacolon and incontinence. Differing degrees of spina bifida have also been noted within the breed, as have pelvic defects, which cause a stilted or stiff-legged gait. Homozygotes die before birth: the moribund **fetuses** can easily be recognized during **gestation** as being abnormally small and globoid, with gross malformations of the **central nervous system**. As with fold cats, it may be possible to select

P.427

against deleterious aspects of the phenotype among the offspring of Manx × non-Manx cats.

Bob-tails

A mutation giving rise to naturally short tails has been reported in various dog breeds, including the Pembroke Welsh Corgi. The molecular basis has been shown to be a mis-sense mutation in a gene for a transcription factor. In a notable **breeding** programme, Boxer breeder Dr Bruce Cattanach back-crossed this mutation into his pedigreed Boxers, obviating the need for tail-docking. Like the Manx mutation, this mutation is lethal when homozygous. However, unlike the Manx mutation, homozygous embryos fail to develop at a very early stage following fertilization, to the extent that all available implantation sites are taken up by normal embryos. Thus, mating bob-tail × bob-tail produces normal litter sizes comprising normal and bob-tailed dogs. In the absence of any apparent deleterious aspect of the bob-tail phenotype, Dr Cattanach has mounted a compelling argument that this is one case where breeding a lethal mutation has no adverse welfare implications.

Hyperkalaemic periodic paralysis

Hyperkalaemic periodic paralysis (HYPP) is a muscle disorder that occurs in Quarter **horses**. It is characterized by reduced tolerance to exercise and intermittent muscle spasms, which can result in difficulty in standing. The disorder is caused by a mis-sense mutation in the gene for the alpha subunit of the muscle sodium channel: a base substitution of cytosine to guanine in the gene causes an amino acid change from phenylalanine to leucine in the transmembrane region of the resultant peptide. This change increases the permeability of sodium across the skeletal muscle cell membrane. Homozygotes show severe episodes of muscle spasm, sufficient to raise welfare concerns. Heterozygotes show just sufficient muscle tone to be attractive in the show ring. Knowledge of the molecular basis of the disorder means that a DNA test is available to distinguish heterozygotes from homozygotes (normals). The welfare concerns can be eliminated by using this test to ensure that each mating involves at least one homozygote-normal parent.

Deleterious mutations that occur naturally at low frequencies

The following represents a small sample of the many deleterious mutations that have been documented in domesticated animals. In each case, the causative mutation has been identified at the DNA level, thereby providing a DNA test for heterozygotes, which in turn provides a simple means of eliminating the disorder - simply ensure that each mating involves at least one animal that has no copies of the deleterious mutation.

Gangliosidoses

Gangliosidoses are a group of autosomal-recessive lysosomal storage diseases. They are due to defective degradation and hence accumulation of gangliosides in the central nervous system. The disorders have been noted in many different species, including cats, dogs, **sheep**, **cattle** and emus. The mutations responsible for these disorders have been characterized at the molecular level in a few of these species. There are two main groups of gangliosides: GM1 and GM2. GM1 gangliosidosis is caused by the deficient activity of lysosomal acid β -galactosidase. Affected dogs have progressive neurological dysfunction and stunted growth and die prematurely. In the Portuguese water dog, the causative mutation is a base substitution of guanine to adenine in the β -galactosidase gene, causing an amino acid change from arginine to histidine in the resultant peptide. GM2 gangliosidosis results from a deficiency of the enzyme β -hexosaminidase. Clinical signs are similar to those for GM1 gangliosidosis, namely progressive neuromuscular dysfunction and impaired growth from an early age. There are two main isozymes of β -hexosaminidase, namely hexA, composed of an α and a β subunit, and hexB, a dimer of β subunits. In cats, GM2 gangliosidosis is caused by a frameshift mutation in the gene encoding the β subunit. As expected, this results in the loss of both the hexA and hexB isozymes.

Glanzmann's Thrombasthenia

Glanzmann's Thrombasthenia is an autosomal-recessive bleeding disorder. It is caused by deficiency of a platelet membrane glycoprotein, which comprises two subunits, αIIb and β_3 . A mutation in the gene for the αIIb subunit is the cause of the disorder in two breeds of dogs. In the Otterhound, a mis-sense mutation in the calcium-binding domain causes the substitution of histidine for aspartic acid within the highly conserved calcium-binding domain, resulting in severe destabilization of the glycoprotein complex. In Great Pyrenean dogs, the disorder is caused by a 14-base insertion within exon 13 of the αIIb subunit gene. This insertion also disrupts the calcium-binding domain; it causes a shift in the reading frame and a premature stop codon.

Factor IX deficiency: haemophilia B

Haemophilia B is an X-linked bleeding disorder resulting from deficiency of the coagulation factor IX. Many different mutations in the factor IX gene have been identified. In Lhaso Apso dogs, the mutation is a deletion of four bases plus a base transition of cytosine to thymine. An affected Labrador retriever was found to lack the gene altogether. A five-kilobase insertion in the exon encoding the catalytic region causes the disorder in Airedale terriers. In pit bull terrier mixed-breed dogs, large regions of the gene have been deleted (approximately 30 kilobases). Yet another mutation in mixed breeds of dogs has also been discovered: a base substitution of adenine to guanine causes an amino acid change, namely glycine to glutamic acid. There are also some cases in other dog breeds where the causative mutation has yet to be identified.

Goitre

Goitre is an enlargement of the thyroid gland that indicates impaired thyroid function. It is seen as a lump at the base of the throat and can become very large. There are two different forms of goitre, one caused by iodine deficiency and the other an inherited form. The latter is found in many species, but the causative mutation has been discovered only in cattle and goats. In Afrikaner cattle, a nonsense mutation in the thyroglobulin gene causes recessively inherited goitre. The causative mutation is a base substitution of cytosine to

P.428

thymine, which causes a codon for arginine to change to a stop codon. This truncates the peptide, rendering it useless in its role as precursor to **thyroid hormone**. In Dutch goats, a nonsense mutation in a different exon of the thyroglobulin gene is the cause of the disorder. Just as in cattle, it also involves a base substitution of cytosine to guanine, causing a codon for arginine to be replaced by a stop codon.

Narcolepsy

Narcolepsy is a disabling **sleep** disorder that affects many animals. The clinical signs include daytime sleepiness, sleep fragmentation, abnormal rapid eye movement (REM) sleep, cataplexy, sleep paralysis and hypnagogic hallucinations. A narcoleptic dog is also likely to collapse from excitement when awake, such as when offered a treat. Canine narcolepsy is caused by mutations in the gene encoding a receptor for hypocretin (otherwise known as orexin). Hypocretins are major sleep-modulating neurotransmitters. In Dobermanns, an insertion of a short interspersed nucleotide element (SINE) upstream from a splice site prevents proper mRNA formation, thereby preventing the formation of the essential peptide. Another mutation has been characterized: a guanine-to-adenine base substitution in a splice junction causes an entire exon to be deleted. Both mutations prevent the proper functioning of the peptide, leading to clinical signs of the disorder.

Citrullinaemia

Citrullinaemia is caused by a deficiency of the enzyme argininosuccinate synthetase (ASS), a vital component of the urea cycle. Lack of the enzyme results in failure of the urea cycle, and hence a build-up of excess nitrogen in the form of ammonia. An affected calf is normal at birth, but signs of **depression** occur within a few hours. The animal has an unsteady gait, its tongue protrudes, it wanders aimlessly, froths at the mouth and usually dies within 3-5 days from ammonia poisoning. The disorder is recessively inherited, and is caused by a nonsense mutation in the ASS gene. The mutation is a base substitution of cytosine for thymine in the fifth exon of the gene. This substitution causes the codon for arginine to be changed to a stop codon, prematurely ending the peptide and rendering the enzyme inactive.

Mutilate

In its broadest sense, the term ‘mutilate’ can mean to alter part of an animal to achieve a defined goal, such as: (i) perceived improvement in appearance (e.g. ear cropping in dogs); (ii) to modify individual behaviour (e.g. **castration** of male cats); (iii) to obtain a certain production quality (e.g. castration of farm animals for leaner meat or avoidance of taint); (iv) to promote better **welfare** for the individual or its group (e.g. castration of lambs); (v) to prevent disease (e.g. docking of sheep and **fly strike**); (vi) to promote harmonious **pet-owner** interactions (e.g. declawing of cats); (vii) for population control (e.g. spaying of female dogs and cats, especially **feral** cats); (viii) to make better sport (e.g. removal of one eye of birds so they fly round in circles in a shoot; breaking the leg or jaw of badgers when baited by dogs); (ix) to prevent escape (e.g. pinioning of captive birds); or (x) to prevent damage to humans (removal of the canine teeth in captive primates). Other disfigurements that could also be classified as a mutilation may occur when marking animals (e.g. **branding**, ear notching, toe clipping). Others may use the term to refer to changes to an animal that are not justified or justifiable (in the user’s opinion) by any benefit gained.

Mutualism

Mutualism is the interaction of two individuals from different species where both individuals gain a **fitness** benefit from the interaction. Mutualistic interactions generally involve the exchange of substances or services that the individuals would find difficult to obtain themselves; thus, behaving mutualistically is advantageous to both individuals. Similar beneficial interactions between individuals of the same species are referred to as expressions of **cooperation**. Mutualism is often

confused with symbiosis and, while some mutualistic relationships may be symbiotic, not all symbiotic relationships are mutualistic.

N

Narcotic

Narcotics (or **opioid** analgesics) are most commonly used in the treatment of acute and chronic **pain (analgesia)**. The pharmaceutical class of opioids consists of many different chemical formulations; however, all are chemically related to morphine. Narcotic medications are highly addictive, and cessation of prolonged dosing of opioid analgesics results in often painful withdrawal symptoms. In order to prevent addiction, narcotics are usually under strict governmental legislative control (e.g. the Controlled Substances Act (CSA) 1970 in the USA or the Misuse of Drugs Act 1971 in the UK) to limit use and availability.

In animal research, narcotics are most commonly delivered via injection, while in human medicine the preferred route is by oral administration. Some narcotics are also available in patch delivery systems or as a rectal suppository. Side effects of narcotics can include drowsiness, nausea, disorientation, dizziness and suppression of respiration and digestion; these side effects must be taken into account when behavioural observations are taken during treatment with narcotics. Tolerance is also another problem of narcotic regimens, occurring over time with prolonged dosing. Tolerance means that the system adapts to the drug and therefore responds less well, requiring increased dosage to achieve a similar affect. The rate at which tolerance occurs, if at all, is specific to the individual, making it difficult to dose consistently in long-term studies.

In animal research, narcotics are most commonly used during anaesthetization and for treatment of pain in animals during and after surgery. Narcotics allow researchers to perform surgical and other procedures on animals while causing them the least amount of pain possible. Narcotics also allow terminal measures and procedures to be taken on animals concurrent with the animals' **euthanasia** following humane protocols. The use of narcotics for the prevention or treatment of pain is generally preferred by institutional animal care and use committees (**see: IACUC**). As narcotic abuse is a common problem with personnel working in close proximity to narcotics, care must be taken to become familiar with and identify the signs of narcotic abuse.

Needs of animals

Animals have needs to the extent that there are resources on which the animals depend, and the lack of such resources will be detrimental for the welfare or even the survival of the animals. Reference is usually made to both physiological and behavioural needs. Physical needs include appropriate nutrition, water, shelter or other means of maintaining the body temperature within a homeostatic range, and an environment that does not result in serious injuries or infections.

Whereas there is agreement over the physical needs of animals that need to be fulfilled to guarantee survival, the definition of behavioural needs has been more controversial. The initial notion that captive animals need to perform all behaviours in their natural behaviour repertoire was soon replaced by an argument based on **motivation**: that animals need to perform those behaviours that they are strongly motivated for. Whether or not an animal is motivated to perform a behaviour depends on an interplay between the different internal and external factors regulating motivation, making it impossible to produce a catalogue of behaviours that are needs and those that are not.

The evolutionary approach favoured by modern applied ethologists assumes that behaviours that have been crucial for survival in the natural history of a species will have been hardwired into the neural system of the animals, and so also remain strongly motivated in modern domestic animals. Failure to satisfy such motivations is assumed to compromise animal **welfare**, thus these motivations are stronger than mere **preferences** or likings. In addition to the satisfaction of needs in the sense specified here, some authors also refer to a wider notion of needs, sometimes called 'comfort needs'. What they have in mind is the possibility that animals' well-being may be further improved by providing them with resources or opportunities that are valued, although the absence of these does not necessarily result in poor welfare.

Negative apperception

Apperception refers to the processes involved in the integration and assimilation of one's own experiences into ongoing cognitive processes (**see also: Metacognition**) - for example, how experience might alter one's beliefs or **perceptions**. Apperception is divided into two processes: positive apperception, in which this process occurs successfully, and negative apperception, in which the process is delayed or unsuccessful. For example, the failure to recognize something for what it is or to learn from experience represents a form of negative apperception. This may be harmful or potentially beneficial to an individual, depending on the particular case. For example, the failure to perceive something as a threat following an **aversive** experience may obviously put an animal at increased risk of harm but, by the same measure, in the case of an individual who is otherwise important to the animal (such as its normal carer), negative apperception after such an experience may help to maintain a functional relationship. Such negative apperception may be explained in terms of prior **reinforcement** schedules or through a more fundamental bias in related cognitive processes, such as **attachment**.

P.430

Neobehaviourism

The original **behaviourism** proposed by Watson rejected mental constructs in animals, and argued that learned behaviour arose only as a result of the direct **reinforcement** of its components, i.e. this suggests that there was no guiding structure in the organization of behavioural acts. Neobehaviourists allow mental states as possible intervening variables shaping the goal of behaviour, but maintain a focus on the relationships between stimuli and behaviour as the only observable data available for scientific study.

Neonatal period

Generally speaking, the neonatal period is the period immediately after birth, although it cannot properly be defined and its length significantly differs between various taxa. The neonatal period is characterized by the highest **mortality** rate in most if not all species. It is sometimes used to refer to a **sensitive phase** during which parent-offspring **bonding** and filial **imprinting** are established.

(RV)

Neophobia

Neophobia is the instinctive **fear** response to novel stimuli. Specifically, it manifests itself as avoidance of new food and/or environmental conditions (including food). Widely observed in rats, neophobia appears to facilitate the ability to associate eating novel food with consequent adverse effects (**see: Aversion; Aversion learning**). Rats are opportunistic foragers and, given the wide range of food qualities they may encounter and the intensity of poisoning pressure to which they are subjected, neophobia is generally assumed to be of adaptive significance. In fact, neophobia was found to be absent among rats of the Hawea and Breaksea Islands, New Zealand, which were historically uninhabited by humans (Taylor and Thomas, 1993). To overcome neophobia, prebaiting (exposure to non-toxic forms of the food vehicle) is now employed as an integral part of most rat-poisoning operations.

The transition from feeding from familiar to novel food after a period of neophobia is usually a gradual process. Wild rats may initially sample only a small amount of food, then gradually increase their intake over time. The interplay of

conditioned aversion and innate neophobia is complex. Indeed, neophobia may actually assist in the development of conditioned aversion (**see: Avoidance behaviour**), by making it more likely that a rat will remember eating novel food, and thereby associate it with adverse consequences (Macdonald *et al.*, 1999). The gradual attenuation of neophobic behaviour is known as '**habituation**'. A neophobic animal can be habituated to novel food or environmental conditions by repeatedly exposing it to that food or environment, as long as the process is not associated with aversive effects.

Nesting behaviour

Nesting behaviour is the behaviour carried out by an animal that is directed at building and maintaining a nest - either for its own use as a resting place or as an environment in which to give birth to live young or to lay eggs. Nesting behaviour has been described in insects, fish, mammals, **reptiles** and birds. Within applied animal behaviour and welfare, nesting behaviour is most often discussed in relation to sows around **parturition**, in hens prior to egg laying and in **rodents** in relation to housing as **laboratory animals**.

Sows

When given the opportunity, sows build farrowing nests prior to giving birth. Prepartum nesting behaviour occurs in wild boar sows and also in domesticated sows in semi-natural environments - as well as indoors in housing conditions ranging from restrictive **farrowing crates** to very environmentally enriched pens. The function of nesting behaviour is to create a secure environment for the piglets.

Studies in semi-natural environments (large enclosures with mixed vegetation) have given insight into the natural prefarrowing behaviour of domesticated sows, which has turned out to be very similar to that of wild boar and **feral** sows. Within the last 1 to 2 days prior to parturition, sows leave their herd: whether the primary motivation is to wander or to leave the herd is unknown. However, **aggression** towards herd members encountered after the herd is left behind suggests that the sows are no longer motivated towards social contact.

The sow often chooses a nest site located just below a slope that is horizontally protected by, for example, a large rock or tree and vertically protected by overhanging branches. Thus, the site is sheltered, while still offering a view of the surroundings. The sow builds the nest by excavating a shallow patch, lining it by scraping grass from the close surroundings into it with her forelegs, collecting nesting materials (e.g. straw, grass, twigs, branches) further from the nest and carrying them in her mouth back to the nesting site. The sow performs many of these gathering excursions and, between excursions, she arranges the materials at the nesting site with nodding, rooting and pawing movements. Nesting can last 2-7 h and is usually complete 1-7 h prior to farrowing. The nest occupation phase lasts until 7-10 days after the birth of the piglets, at which time the sow and the piglets rejoin the herd.

Sows housed in production environments are also motivated to nest build. In outdoor systems and extensive indoor pens with large space and appropriate nesting materials, the behaviour is almost identical to that of sows in semi-natural environments and wild boar and feral sows living in the wild. Even in farrowing crates, which impose severe locomotory restrictions, most of the behavioural elements known from nesting in unrestrictive environments can be observed when the sow is given nesting materials. In crates, as well as in pens, nesting behaviours can also be seen when sows are given no

nesting materials at all. The behaviour is then referred to as redirected or in-vacuum nest building.

The control of nesting seems to involve both internal and external regulation, but the exact mechanisms are still unknown. It has been suggested that the hormone **prolactin** is responsible for initiating nest building, because there usually is a concurrent rise in prepartum plasma prolactin and nesting behaviour. However, recent studies have shown that nesting can occur without a rise in prolactin. Other hormones that have been suggested to be implicated in the regulation are **prostaglandin F₂-alpha** and oxytocin. Several studies have shown that environmental feedback from the nest acts in concert with the hormonal control, e.g. nesting starts sooner when nesting materials are readily available, and may end sooner in relation to parturition when appropriate nesting materials can be used.

The fact that sows perform nesting behaviour in very different environments shows that it is a highly motivated behaviour. This, in combination with the element of internal regulation, has led to the contention that nesting in sows is a **behavioural need**. Hence, the lack of opportunity for prepartum nest building due to locomotory restrictions and/or lack of nesting materials is widely recognized as a welfare problem in sows.

Hens

A hen will search for a suitable nest site before laying an egg. In nature, this nest site will usually be some distance from where the other hens are but, under commercial conditions (**see: Laying hen housing**), hens will actively choose to nest close to other individuals. The results from **preference** tests show that breeds, and even individual hens, have specific preferences for colour, types of substrate and light intensity of the nest site. However, in general, hens will prefer an enclosed nest site rather than a more natural nest, and one with deep substrate over one without. Once a preference has been established, the hen will often return to the same location time and time again. There is also a well-known preference for hens in loose-housing systems (in which the nests are placed in rows) to lay eggs in the end boxes. The reason for this preference is not clearly understood.

Experiments have shown that hens that do not gain access to an appropriate nestbox will show more gakel calls (usually thought to be a sign of **frustration**), more pacing and a higher proportion of abnormal eggs (a sign of **stress**) than hens with a nest site. Hens are also prepared to work hard to gain access to a good nestbox. Taken together the evidence suggests that access to a suitable nestbox is a strong need in the hen.

The nest-building behaviour of **chickens** is less well investigated than that, for example, in sows. Nest building in chickens is performed by the hen first glancing at and examining the nest site (this phase might take a long time); she will then sit down and perform a series of movements by which she moves material towards her (bill raking and litter gathering), and shapes the surface under her by rotating her body and scraping her feet sideways.

What little evidence there is suggests that hens will attempt to build a nest irrespective of whether it has a preformed nest or not, i.e. it is the behaviour of building the nest rather than the consequence of the behaviour that is important for the hen. However, in experiments in which hens have had the possibility of choosing a mouldable surface with and without litter, no preference was detected; nor was there a preference for mouldable over non-mouldable nests. The scant evidence, therefore, points to a need for a mouldable or pre-moulded nest, but not necessarily for access to nest-building material.

Laboratory rodents

The common laboratory rodents - **rats** and mice - will both build nests if given the opportunity. Traditionally, laboratory housing has not provided bedding material due to concerns about hygiene and the ability to observe the animals at all times. More recently, however, welfare concerns have driven research into the provision of nesting materials. Mice in the wild build dome-shaped, complex, multilayered nests, but this behaviour is rarely seen in the laboratory, perhaps due to inappropriate nesting material rather than the nest-building ability of the **mouse**. If mice are given shredded paper strips, they can build complex nests. Nests are of poorer quality if nesting material is in the form of tissue paper or compressed cotton squares.

Unlike adult mice, adult laboratory rats without prior experience of nesting materials will not nest build spontaneously when materials are provided. However, wild rats are known to build complex nests from a variety of materials. If rats are given access to materials from birth, compared with receiving their first experience later in life, they will build more elaborate nests and waste less material, indicating that nesting behaviour in rats has a component that is acquired through experience. Overall, provision of bedding for nesting has been linked to decreased variation in measured parameters during experimental studies, which may thereby contribute to a reduction in the number of animals needed for quantifying a given scientific procedure.

Neurectomy

A neurectomy is the removal of a section of a nerve in order to destroy the ability of the nerve to transmit sensation from below the operative area (**see: Denervating**). Neurectomy is not often performed in modern veterinary medicine, because non-steroidal

P.432

analgesia makes it possible to relieve **pain** without recourse to surgery. It was formerly one treatment for diseases of the lower limb. Neurectomy was sometimes performed to prolong the usefulness of a **horse** by relieving the pain of a chronic incurable condition. Perhaps more importantly, from a **welfare** point of view, it relieved the pain. The worst sequela to neurectomy is development of an infection that will go unnoticed because the horse does not feel the pain and, therefore, will not limp (i.e. be lame).

The nerve sectioned depends on the **lameness**. For example, a bilateral posterior digital neurectomy is performed when a horse has navicular disease (disintegration of the navicular bone, a sesamoid bone found in the posterior hoof). Sixty per cent of horses are sound (not lame) 1 year after neurectomy. Volar neurectomy is used when a horse has osteoarthritis of the interphalangeal joints (ringbone) or ossification of the lateral cartilages of the third phalanx (sidebone). The volar nerve can be cut just before it divides into its anterior and posterior branches; this will interrupt sensory information from the hoof. Alternatively, the median nerve can be incised, because a branch of the ulnar nerve is spared when a volar neurectomy is performed. Most neurectomies are performed on the forelimb, because that is the site of most chronic lameness; however, the tibial nerve can be incised to prolong the usefulness of a horse with a chronic incurable lameness of the hock or the distal portion of the limb. Infra-orbital neurectomies have been recommended for head shaking in the horse, but the response to treatment is generally unreliable.

(KAH)

Neuroethology

Neuroethology refers to the mechanistic study of the biological processes regulating the expression of behaviour, and tends to emphasize the phylogenetic and comparative evolutionary aspects of the neurological systems controlling behaviour. The

discipline has its own academic society, the International Society for Neuroethology (see <http://www.neuroethology.org> for details).

(DSM)

See also: Comparative psychology; Ethology

Neuron(e)

A neuron(e) is the basic cellular communication and information-processing unit of the nervous system. Anatomically, a neuron consists of three parts: (i) the cell body (perikaryon or soma), with a nucleus and various organelles; (ii) the axon (nerve fibre), with its ramiform terminals (synaptic boutons); and (iii) the dendrites, with their branches (dendritic tree) and spines. Functionally, a neuron detects and integrates stimuli from the internal and external environments, and transmits the signals from one location to another along its axon, resulting in sensory and motor reactions that permit an animal to appraise, enter and exploit its environment.

(H-WC)

Neuronal plasticity

Neuronal plasticity is the capability of **neuron(e)s** to adapt cellular characteristics anatomically and/or functionally in response to changes in the internal and external environments. The plasticity is maintained throughout life, which is a prerequisite for recovery of physiological functions following **injury** or **disease** in the **central nervous system (CNS)** affecting animal behavioural and physiological **homeostasis** and well-being.

Environment plays an important role in the development of the nerve system: for example, in morphology, extending the dendritic trees and/or formation of axon collaterals with boutons and synapses; and in physiology, changing the expression of receptor genes and receptor densities as well as synthesis of neurotransmitters and their release. Compared with tame animals of the same species, wild animals have larger **brains**. This phenomenon is related to differences in the amount of learning: life in the wild requires a much broader repertoire of **adaptive** behaviour.

In **laboratory animals**, more increases in both dendritic ramifications (arbors) and the number of synapses are found in the cerebral cortex of rats raised in a simulated natural environment with ample space and access to toys than in rats raised in standard laboratory cages. Following damage to the CNS, the survival neurons sprout their axon terminals, extend their dendritic tree and/or increase the number of spines, resulting in an increase in conducting or receiving signals per neuron. Through these changes, the lost neurons' functions are replaced by the survival neurons, and the pathophysiological balance is maintained.

(H-WC)

See also: Enrichment; Housing

Nicking - tail

Tail nicking is a procedure in which the ventral muscles of a **horse's** tail are cut (myotomy). The purpose of this is to decrease the ability of the horse to lower or abduct its tail. It is performed on some **breeds** of gaited horse - horses that perform a rack or running walk in addition to the natural gaits of walk, trot and canter. After the myotomy is performed, the tail is held vertically by a harness so that it will remain in that position during competition. The procedure is illegal in some countries, there being two **welfare** issues: (i) the **pain** of the initial incision; and (ii) the discomfort of constantly wearing a harness. Apparently, horses learn to roll wearing the harness. The breed to which tail nicking and harnessing is most often applied is the American saddlebred. This breed was developed by crossing Thoroughbreds with Narraganset pacers, a breed that paced (moving both hind and fore limbs forward at the same time). The harnesses reduce comfort, and tail nicking is an unnecessary **mutilation**.

(KAH)

See also: Docking - tail

Nociception

Nociception is the underlying mechanism by which an animal feels **pain**. The nociceptive system and the feeling of pain are normally inextricably linked. The nociceptive system comprises three types of peripheral nociceptors that respond to excess pressure (mechanonociceptors), excessive temperatures (thermonociceptors) or chemical release (chemonociceptors). They connect to the **central nervous system** by both myelinated (A delta) and non-myelinated (C) fibres.

There are three **neuron(e)s** involved in the transfer of impulses from the peripheral nociceptors to the cerebral cortex, where any pain is actually felt by an individual as a noxious event (**see: Feelings**). First-order neurons synapse (connect with another neuron) in the dorsal horn of the spinal

P.433

cord with second-order neurons. The nerve axons from the second neuron then cross over to the opposite side of the cord and pass up to the thalamus in the **brain** (forming the spinothalamic tracts). In the thalamus they synapse with third-order neurons that connect to the cerebral cortex (thalamo-cortical tracts), where pain is felt and located to the originating part or region of the body where the nociceptors were activated. Neurons in the dorsal horn also synapse with descending inhibitory fibres from the brain that modify the passage of nerve impulses to the brain.

These synapses may mitigate the level of pain experienced by permitting (so-called gating) only impulses of a certain frequency to pass on upwards. These descending fibres grow down the spinal cord in the first week or two after birth (this has been demonstrated in **altricial** animals but not in **precocial**). Consequently, as these descending inhibitory fibres have not yet grown down and synapsed in very young animals, it is likely that they are more sensitive to noxious stimuli than older animals and adults in whom the nervous system has matured. Synapses in the thalamus also modify the cerebral response through learning and **memory** and may heighten pain felt in anticipation - e.g. going to the dentist. In the abdominal organs there are stretch receptors that, when stimulated, are able to induce a feeling of pain known as colic. These are routed to the brain by afferent sympathetic and parasympathetic components of the **autonomic nervous system**.

Nocturnal

Nocturnal animals sleep during the day and are active at night, the opposite being **diurnal**. Nocturnal animals generally have well-developed senses of smell and **hearing** and the ability to see in low levels of lighting. Animals may adapt to following a nocturnal schedule for such reasons as to decrease the risk of **predation** or to avoid the heat, and resulting water loss, of the daylight hours. In some cases animals may adopt a nocturnal pattern of activity as either a lifetime or cultural adaptation; for example, some populations of elephants appear to have developed a more nocturnal activity in response to historical **hunting** activity/pressure.

(LMD)

Noise disturbance and hearing

The term 'noise disturbance' typically refers to loud anthropogenic sound that is not a natural part of an animal's environment. Noise disturbance is of growing concern among wildlife managers, as the potential impact on the social and ecological needs of both captive and **free-range animals** is integrated into **conservation** and management strategies. Anthropogenic noises that are a by-product of industrial, military, construction or vehicular activity are typical sources that prompt concern, promote research and drive the development of protective regulatory measures.

Chronic or severe noise may negatively impact wildlife in various ways. Richardson *et al.* (1995) defined 'zones of noise influence' as (listed from lowest to highest impact):

- Zone of audibility, wherein an animal hears the noise. This is limited by both normal ambient noise and audibility.
- Zone of responsiveness, whereby an animal responds to the noise either behaviourally (e.g. withdraws from source or changes current behaviour), physiologically (e.g. a change in **heart rate**, breathing pattern or hormonal **stress** response) or is displaced from a location.
- Zone of masking, which encompasses noises that may cover up important sounds such as social **communication**, predator/prey or environmental cues.

- Zone of **hearing** loss, discomfort and **injury**, which includes injuries such as temporary threshold shifts or permanent loss or impairment of hearing. This last zone typically requires close proximity to high-amplitude sound, such as the shock waves produced from explosives.

The zones of noise influence listed above (especially the first three) are limited by audibility of the noise, and so an animal's hearing ability fundamentally determines whether a noise is in fact a disturbance. Hearing is a perceptual phenomenon. Each vertebrate species has a unique capacity to hear sounds that are informative as well as those that are not. The latter type of sound is regarded as *noise*. Hearing is a component of the acoustic communication system that includes: signal propagation (**vocalizations**), signal pathway (habitat) and signal reception (hearing). Hearing allows an individual to receive social signals from **conspecifics**, location information from predator or prey or environmental cues that indicate weather change, topographic features or impending danger. This balance of social, resource and environmental cues is unique from species to species and fosters the development of species-specific perceptual abilities.

Sound is propagated through the environment in the form of pressure waves. These waves may be described in terms of amplitude, perceived by humans as loudness, and frequency, perceived as pitch. An animal's hearing sensitivity is defined as the ability to detect sounds at the lowest possible amplitude over a range of frequencies. Signals that are important to a species must have a frequency content within the hearing range, which in mammals varies considerably by species. Hearing sensitivity is illustrated by a function called an 'audiogram'. The mammalian audiogram is usually shaped like a 'U', with the greatest sensitivity (i.e. best hearing) in the middle of the range.

Audiometric measurements can also be used to develop frequency-dependent weightings of environmental noise. With this information, estimates of exposure can be tailored for particular species and predictions can be made regarding the noise impacts. For example, audiograms for humans have long been established, and these parameters have been incorporated into what is called 'A-weighting'. A-weighting is the standard that organizations such as health and safety bodies use when developing safety guidelines for noise levels encountered in the workplace. In humans, A-weighting reduces the variability in correlations between exposure and responses, improving predictions significantly. An estimation of equal-loudness perception is derived by defining hearing thresholds across frequencies (the audiogram) and then measuring the time it takes for an animal to respond to a sound (response latency).

In nature, animals are exposed to a wide variety of sound sources. The distribution of sound levels at various frequencies is specific to different environments, but a great deal of

P.434

variability may be expected over the course of an animal's lifetime. From a theoretical point of view, animals are assumed to be adapted to cope with levels of noise typical in their natural environment over a lifetime. Noise stimuli that are not a 'natural' part of an animal's environment may constitute a noise disturbance, especially if the noise **stimulus** is in the range of best hearing or maximum sensitivity for that species.

At extreme exposure levels, noise can damage hearing and compromise intraspecific communication (see the last two zones of influence, above). Based on laboratory studies, chronic exposure to elevated noise may promote a stress response that can inhibit normal behavioural and physiological functions, although the literature is inconsistent and the conditions that give rise to stress are very poorly understood. The results of studies done *in situ* in wildlife habitat have been mixed as well. *In situ* studies have typically assessed the impact of relatively short-term exposure to aircraft, vehicle traffic or construction disturbances on wildlife. As a general rule, the literature suggests that short-term behavioural and physiological responses occur, but does not provide consistent evidence for long-term physiological effects. In cases where population-level effects have been suspected, appropriate controls were not available, so that habitat effects could not be eliminated as an explanation for the correlation between noise and population-level effects. At present, it is fair to say that very little is known about the long-term impact of noise disturbance on populations.

Predictive mathematical models illustrating the possible impacts of anthropogenic noise are useful in assessing the potential negative impacts of noisy activities on animal populations. However, the value of these models is limited by the dearth of knowledge on the hearing capacities of individual species. Additionally, a thorough knowledge of the role of acoustic communication is needed to address the potential impacts of noise on social and reproductive processes.

Norepinephrine

Norepinephrine (noradrenaline) is a **catecholamine** and is classified within the amine neurotransmitter group. Upon stimulation of the **sympathetic nervous system**, norepinephrine is synthesized and released from post-ganglionic nerve terminals to bind to α_1 -, α_2 -, β_1 -, β_2 - and β_3 -adrenergic receptors. Activation of these receptors on or near effector tissues causes smooth muscle constriction or dilation, dependent upon the specific tissue. Sympathetic nerve activation occurs in response to stimuli such as **fear, pain, anxiety and stress**.

In a stress response, norepinephrine released from nerve terminals binds to α -receptors on smooth muscle surrounding the vasculature to cause vasoconstriction in a matter of seconds. Dependent upon the region of visualization, blood flow can be decreased from 'non-essential' tissues, such as the skin or gastrointestinal tract, or blood flow is increased by increasing **blood pressure**. An increase in blood flow is critical in the stress response and, by sympathetic activation, norepinephrine released from **neuron(s)** in the heart binds to β_1 -receptors to cause increased force of contraction, increased conduction velocity and increased **heart rate**. Not all norepinephrine is released from post-ganglionic sympathetic neurons. Upon stimulation of the sympathetic nervous system, the medulla of the **adrenal gland** is stimulated to produce predominantly **epinephrine**; however, epinephrine and norepinephrine are produced in a ratio of approximately 8:1. This norepinephrine is then released into the general vascular circulation, where it can affect all cells containing adrenergic receptors.

Like epinephrine, norepinephrine can be a useful measurement for researchers when assessing animal **welfare**. This is due to the fact that norepinephrine is consistently elevated in circulating blood when animals are exposed to **aversive** stimuli such as electric shock, **restraint** and **injury**. In contrast to epinephrine, which is released directly into the peripheral vasculature, only a minor proportion of norepinephrine is released into the blood, and the total norepinephrine measured in the blood is largely influenced by 'spill-over' from nerve terminals. The measurement of norepinephrine is faced with the same challenges as that for epinephrine.

(DCL)

Novel object test

The novel object test is an object **recognition** test used to study learning and **memory**, commonly in rats and mice. The procedure involves exposing the animal to a distinct environment containing two identical objects (such as plastic, glass or ceramic items) for a few minutes. The time spent exploring the sample objects is recorded. Following sample object exposure, the animal is returned to the home cage for a retention period (usually for between 1 min and 4 h). The animal is then returned to the test environment, in which one of the familiar objects has been replaced with a novel object (or has been displaced in space), and is allowed to explore for 3 min, during which time exploratory and locomotor activity is recorded. Rats and mice have a tendency to approach and explore novelty (neophilia), and the ability to discriminate between a familiar and a novel object (indexed by the time spent exploring the novel object) indicates recognition of the previously experienced object. This test has been used to examine memory function after drug challenges, brain lesions or targeted gene **mutations**, and as a function of **ageing** and development.

Novelty

Novelty means being new or having newness. A **stimulus** is only novel if the animal is not habituated to it. Once a novel stimulus is presented to an animal, the stimulus begins to lose

P.435

its novelty. It is therefore not an objectively measurable or quantifiable feature of a stimulus in the way we might describe shape, colour or loudness, but instead it relies on the 'interaction between stimulus and perceiver'. A yellow ball will be yellow and spherical to every animal, but only 'novel' to those that have not had exposure to it. Additionally, the degree of novelty may be influenced by the animal's previous experience with similar stimuli, the time since exposure and the duration of that exposure. For example, a yellow ball may be less novel to animals with experience of, say, a blue ball compared with animals that have not been previously exposed to any ball.

Although the desire to seek novelty is a fundamental behavioural tendency in many species, exposure to novelty can induce both negative and positive emotional and behavioural reactions and either avoidance or approach. It has been proposed that the response is dependent on the degree of novelty. First, intense novelty can induce a **fear** response and **avoidance behaviour (neophobia)**. Mild novelty may cause interest, trigger approach (neophilia) and give positive reward. Low novelty may generate no interest and likewise result in avoidance. Thus, a curvilinear relationship probably exists (see Fig. N.1).

This picture is further complicated not only by the degree of novelty within the environment as a whole, but also by species differences. For example, a novel object encountered in a familiar environment may elicit a different response compared with the same novel object encountered in an unfamiliar environment. Also, depending on the species, the response to a novel object that induces high levels of fear may be quite different. The animal may engage in active defence and approach to attack the novel object; it may engage in passive avoidance and become immobilized, neither approaching nor moving away from the object; or it may engage in active avoidance and actively move away from the object.

Experimentally, in applied animal behaviour, response to novelty has been used extensively to assess fear and also to determine '**personality**' or '**temperament**'. Exposure to novelty has been achieved by either placing the animal alone into a novel arena (an **open-field test**) or presenting a novel object to the animal in a test arena, with the test arena often being the open-field arena but also sometimes being the home pen.

Fig. N.1. Hypothetical relationship between the novelty of a stimulus and approach/avoidance behaviour (from Hughes, 2007).

With open-field or novel-arena tests, the types of measures that are often taken include activity (e.g. number of grid squares crossed), amount of time spent in the pen periphery, amount of time spent in the pen centre, time spent immobile, number of **defecations**/urinations, total distance travelled, number of escape attempts and the number and type of **vocalizations** performed. The behavioural measures may be combined with physiological measures such as **heart rate** and circulating cortisol, **prolactin** and **oxytocin** levels. For novel object tests, all these measures can also be taken and used in combination with measures of direct response to the object - i.e. latency to approach within a certain distance, latency to make contact with the object, number of contacts or total time spent in contact with the object.

In general, novelty tests have been adapted from those used with rodents and applied to other species without validation as to what exactly they are measuring. Behaviourally, farm animals are quite different from rats and mice, and thus the conclusions drawn from farm animals' behavioural responses to novelty cannot be extrapolated from similar responses of rodents. The novel arena is usually an open enclosure, which may be square, rectangular or circular in shape.

The dimensions of pens used experimentally vary quite considerably, being perhaps as small as 1-2 m² and up to >200 m², largely depending on species but not always. Thus, the arena may be seen by poultry as an environment that could lead to increased **predation** risk, and by ungulates as a confined space. Novel objects that have been used are equally varied, including buckets, balls, traffic cones, umbrellas, etc., but, almost exclusively, objects that have no evolutionary context. Not surprisingly, the reliability and validity of these tests is open to question, and often there has been poor repeatability and low or no correlation between measures both within and between tests.

Noyau social organization

Noyau social organization is characterized by a primarily solitary lifestyle, with overlapping home ranges between the sexes. Adult males typically have larger home ranges that encompass the ranges of several adult females. Temporary social groups are formed between a female and her offspring. Synonymous with dispersed mating, noyau is considered one of the simplest social structures and is observed among prosimians and **orang-utans**.

Nursing

The terms 'nursing', 'suckling' and 'sucking' are used inconsistently in applied **ethology**. Quite often, nursing refers to what the mother does when she gives milk to her young, and suckling refers to the behaviour of the offspring. Some authors use the word suckle for the maternal aspect of the interaction,

and the word suck for the offspring behaviour. In this article, nursing will be used to refer to the whole of the interaction, i.e. the complex of closely intertwined physiological and behavioural processes in both the mother and the offspring.

Nursing is the natural way for mammalian mothers to provide nutrition for their offspring during the first period of life. In each species, anatomical, physiological and behavioural adaptations have evolved so that the specific nursing pattern is fitted to the life history, the reproduction strategy and the social and physical environment in which the species naturally lives.

Anatomy of nursing

In all placental mammals, milk is produced in milk alveoli, from where it is transported to the teat openings via milk ducts. In relation to nursing pattern, the most important difference in milk gland anatomy is between ruminant species that possess milk cisterns - i.e. caverns that store part of the milk produced between the nursings - and other mammals that do not have cisterns. Usually, the milk stored in milk cisterns can be withdrawn just by stripping (compression of the teat cistern from its base to its teat), combined with sucking (underpressure applied at the opening of the teat canal or milk ducts), whereas the milk accumulated in milk alveoli needs to be expelled through a contraction of the myoepithelial cells surrounding the alveoli (milk ejection).

Female mammals have one to eight pairs of mammary glands, and the number of teats normally equals or exceeds the number of young in a litter. This adaptation secures milk supply for all surviving offspring, although competition can still occur for the most productive teats. Artificial **selection** for high litter size can result in a situation (such as the one in the domestic pig) where the number of offspring surpasses the number of teats, leading to more intense competition and increased **mortality** among the young.

The position of the teats corresponds to the usual nursing position of the species, e.g. primates that nurse in a sitting position while their young cling to the ventrum of the mother have sternal glands, whereas ruminants have glands in an inguinal position. In those dairy cattle breeds that underwent an intense period of breeding for high milk yield, the teats of the unnaturally voluminous udder are positioned so low that neonatal calves have difficulty in finding the teats by themselves and often fail to drink the **colostrum** if not assisted.

Physiology of nursing

A specific hormonal state is necessary in the female mammal in order for **lactation** and nursing behaviour to be initiated. **Prolactin** is the hormone needed for lactation initiation and maintenance in many mammalian species. However, once nursing behaviour is initiated, it does not seem to depend directly on the female's hormonal state; rather, it seems to be regulated by chronobiological, motivational, reflexive and cognitive processes.

The release of milk (milk ejection) is caused by the contraction of milk alveoli in reaction to an increase of oxytocin in blood. The whole causal chain involves several steps. First, unconditional stimuli (such as tactile stimuli from the pre-ejection teat massage) or conditional stimuli (such as seeing the baby or hearing its voice) are transmitted via the sympathetic nervous connections to the **hypothalamus**. In reaction to this stimulation, oxytocin is secreted from the hypothalamic cells and released to the bloodstream from the rear part of the **pituitary gland**, called the neurohypophysis. Some species such as the pig have a refractory period after each milk ejection, i.e. another milk ejection cannot occur before a certain interval elapses since the previous ejection (about 15 min in the pig). The mechanism of this block resides somewhere in the transmission of the ascending stimuli to the descending hypothalamic command because, during the refractory period, the oxytocin release and milk ejection can be induced by direct hypothalamic stimulation but not by tactile stimulation of the glands.

After emptying of the glands during a nursing bout, milk production in the glands starts anew at the full speed. As the gland gradually refills, the speed of milk secretion slows down. This has the consequence that if intervals between nursings become prolonged, the total milk production (per day) is reduced and the young obtain less milk. When a teat is not used for a certain period of time (usually several days), the milk secretion in the glands connected to it stops altogether - the teat dries up and the process of mammary involution starts. The negative feedback process is mediated through inhibitory substances contained in the milk, reduced blood flow to mammary tissue and the pressure of the accumulated milk on epithelial cells. Nursing behaviour thus has a crucial feedback effect on the physiology of milk synthesis and secretion.

The act of nursing is accompanied by dynamic hormonal release. In the dam, oxytocin, prolactin, **insulin** and somatostatin concentrations increase, peak and then decrease in the blood during or within 60 min of nursing. In the sucking offspring, **glucocorticoids**, **endorphins**, **cholecystokinin**, oxytocin and insulin, among other hormones, are released in connection with nursing. Often it is not (just) the release or ingestion of milk but rather the performance of the nursing/sucking behaviour that triggers the hormonal surge. The hormones released during and after nursing modify the catabolic/anabolic

balance of the mother's metabolism, affecting her further milk production; for the young the hormones enhance the digestion of milk; and, in both the dam and the offspring, they provide internal reward, thus increasing further the motivation to engage in nursing.

The mother is alert or even aroused during the nursing in some species like the pig; or she may behave indifferently, e.g. a late-lactation cow that grazes while nursing a calf; or nursing may occur during a somnolent state such as in the rat.

Time structure of nursing

Three hierarchical levels of time structuring of the nursing behaviour can be distinguished. First, a nursing bout has a specific inner time structure related to the timing of milk flow. Secondly, nursing bouts occur at predictable intervals, creating a species-typical rhythm of nursing. Thirdly, nursing behaviour changes during the course of lactation.

Time structure of a nursing bout

The structure of a nursing bout typically consists of: nursing initiation, an introductory pre-ejection phase, a period of milk flow, a post-ejection non-nutritive phase and the termination

P.437

of nursing. The nursing can be initiated by the young, when they approach the mother and solicit nursing through **vocalizations** and/or attempts to nuzzle the teats; alternatively, the dam can start the nursing through calling the young (e.g. grunting in the sow, bellowing in the cow, seeking them out in **hider** species like the red deer or the rabbit, and assuming the nursing position (lying on the side by the sow; crouching over the young in the rat).

After making contact with the nipples, the young start to stimulate them by nosing, sucking, butting (cattle) and/or pawing (rat). This stimulation usually lasts several tens of seconds to several minutes before it triggers milk ejection. The young then switch to intensive sucking and swallowing of the milk. This nutritive phase of the nursing bout can be as brief as 15 s (in the pig) or as long as 5 min or more in cattle.

In some species such as the rabbit, nursing is terminated by the dam immediately after milk flow ceases; in most species, the young remain in contact with the nipples for a further period of up to several minutes. This post-ejection non-nutritive phase is often characterized by similar types of behaviours to those seen in the introductory phase. The termination of nursing may be gradual, such as when piglets fall asleep at the udder, or abrupt, such as when the sow rolls over on her belly or stands up.

Nursing in some species does not contain all the phases: for instance, in the rabbit the mother enters the burrow and crouches over the pups, which orient to the nipples (using pheromonal and tactile cues) within a few seconds. The milk flow phase starts immediately and is ended abruptly after 3-4 min by the doe jumping out of the burrow. In other species, such as rats or humans, a nursing bout may contain more than one milk flow phase.

The switch from one phase to the other is usually triggered by a specific **stimulus**, e.g. oxytocin is released after there has been enough stimulation by the young, or the intense sucking phase in the calf starts when the first milk is tasted. In some cases, though, the duration of a phase seems to be internally fixed. For instance, once milk ingestion has started in a calf, the very intense **motivation** to suck lasts for a pre-set period of 5-10 min.

The duration of a nursing bout is not a good indicator of the amount of ingested milk. Sometimes the relation can even be negative, such as when low milk intake stimulates the young to prolong the post-ejection phase of the bout.

Nursing intervals and synchronization

The frequency of nursing varies widely among species. Rabbit mothers visit their young once per day to nurse them, whereas a sow gives milk about 30 times a day at the beginning of lactation. The timing of nursing may have a more or less pronounced **diurnal pattern**. For example, lactating cows have a prominent peak in nursing activity early in the morning at the end of the night rest, and otherwise nurse about six times a day at quite regular intervals; a rabbit doe nurses at an individually specific time in the night and the pups prepare for her coming 1 h in advance. In the pig, there is little difference between the inter-nursing intervals during the day and in the night.

In group-living mammals, females tend to synchronize their nursing. For instance, if two lactating sows are housed in one room, they nurse within 1 min of each other in about 90% of cases and, even in larger groups of sows, the nursing synchronization is prominent and much stronger than the synchronization in general activity (**see: Social facilitation**). This

synchronization probably evolved to enable group cohesion during alternating of foraging and nursing, but may also be a maternal strategy to reduce allosucking by alien piglets.

Changes in nursing behaviour during lactation

From the biological fitness point of view, nursing is crucially important for both the mother and the young. Maternal investment is very high during lactation (substantially higher than during **gestation**), and this investment decreases her prospect for further survival and reproduction. For the offspring, milk supply is absolutely critical for survival during the early suckling period, but less so later in lactation when they combine foraging for solid food with milk intake. The changing balance between the accumulating maternal investment and decreasing importance of milk for the young is reflected in the nursing behaviour. The frequency of nursing declines during the lactation, and signs of behavioural conflict become more common: the nursings are increasingly initiated by the young, and terminated by the mother; the young attempt sucking even when the mother is busy with another activity; and the mother may nurse in a position that gives less access to the teats for the young, such as the standing posture in the pig.

Communication during nursing

Since nursing is an interactive process, **communication** between the mother and the young is of paramount importance. All sensory channels could be used during the nursing, but acoustic, tactile and olfactory communication prevails. In the mother's acoustic signals, information about her identity, location and timing of nursing phases is often included. For instance, the nursing sow produces typical rhythmical grunts. The inter-grunt intervals and spectral composition of the individual calls contain information about the dam's identity; the abrupt start and end of each call enable an easy localization; and a typical increase in the grunting rate announces an imminent milk ejection. The young most often vocally signal their identity (through frequency-modulated calls that function like 'signatures') or a disruption in the milk intake process ('protest' screams of a piglet that has been displaced from its teat by an intruder). Tactile stimuli (prolonged/intensive teat nuzzling and/or butting) are typically used for the communication of need.

Olfactory communication primarily serves to identify the progeny to the mother. Calves, foals, lambs and goat kids typically suckle in the anti-parallel position, i.e. access the udder from the front while having lateral contact with the mother's body and swinging the tail to increase odour dispersion.

Behaviours that enable identification of the young by the mother are often part of the introductory and milk ingestion phase. For example, calves often pass under the chin of their mothers before going to the udder; piglets wander to the snout of the nursing sow during the introductory phase - and especially just after milk ejection - and make close naso-nasal

P.438

contacts with the mother (sometimes even putting the nose into the mother's open mouth) while producing specific croaking calls, and mothers repeatedly sniff their suckling young during the nursing bout, concentrating particularly on the anogenital region.

Non-nutritive nursing

As has been already described in the section above on the time structure of nursing, there are non-nutritive phases included in each nursing bout. However, some nursing bouts do not contain any milk let-down and the young are not able to obtain any alveolar milk during those bouts. These non-nutritive bouts may be due to external disturbance in some cases, such as with the **epinephrine**-caused blocking of milk ejection in the cow. In the pig, non-nutritive nursings are part of the normal behavioural repertoire and are probably a way of bargaining the level of milk investment between the sow and the litter.

Allonursing

As a rule, a lactating female would only nurse her own offspring. However, allonursing (giving milk to young that are not the biological offspring of the dam) can occur due to a number of mechanisms. A mother may make a misdirected attachment (sometimes labelled '**mis-mothering**') to an alien young during the sensitive postpartum period and then nurse it as her own offspring. Alternatively, mothers may tolerate the sucking by alien offspring even though they recognize them correctly. For instance, some beef cows allow alien calves to suck together with their own progeny. Thirdly, mothers may aggressively repel alien young, but do not succeed in avoiding all allonursing because it is not possible to check the identity of all young at each nursing (such as is the case in the pig) or because the allosuckers break through the defence from time to time. The latter occurs, for instance, when a calf 'steals' the milk from an alien dam - it is sucking together with the

biological offspring, reaching the udder from the side or from behind so that the cow cannot access it for olfactory identification.

One specific form of allonursing is communal nursing. Two female house mice, for instance, give birth in the same nest and then nurse the two mixed litters indiscriminately.

Some forms of allonursing (such as mis-mothering) can be maladaptive, i.e. they decrease the **fitness** of both the dam and the young. Sometimes allonursing is beneficial for the young but not for the female, such as when piglets from a very numerous litter succeed in allosucking at another sow. Finally, allonursing may be an adaptive strategy also for the 'foster' mother due to **reciprocity** (e.g. communal nursing in mice) or due to **kin selection** (e.g. nursing orphaned or weak offspring of a relative female).

Nursing behaviour and welfare

Species-specific patterns of nursing have changed relatively little during the process of **domestication**. In the natural environment, both the female and the young use the available space to assume appropriate nursing/sucking position and to bargain the initiation and termination of nursings through moving towards or away from each other. When movement is restricted in **captivity**, abnormalities can occur, leading to **welfare** problems. Improper design of crates for lactating sows (e.g. horizontal bars low above the floor) prevents full access to the udder and thus disturbs the nursing order among the piglets. Crated lactating sows are not only heavily confined (**see: Confinement**), but cannot walk away when the litter demands over-frequent nursing later in lactation. This results in chronic stress in the sows and forces them to use alternative strategies such as spending a lot of time lying on their belly.

(MS)

Nutritional wisdom

The concept of 'nutritional wisdom' historically has been taken to mean that animals possess the ability to detect and identify internal dietary deficiencies and seek out appropriate food items to correct the internal imbalance. This led to the original hypothesis that animals possessed specific hungers for nutrients, e.g. a hunger for salt or protein.

Influential evidence for this initial hypothesis came from Richter's studies, carried out in the 1930s/40s, on cafeteria feeding with rats. Richter demonstrated that rats immediately altered their food selection patterns in order to rectify a response to an artificially induced nutrient deficiency or a requirement for nutrients through changes in physiological state. Richter's work was later criticized on the basis that animals would require a specific appetite for each of the numerous micro- and macronutrients. However, in partial support for Richter's assumptions, there is evidence to suggest that certain animals are able to correct a sodium deficiency, and moose have been observed to skew foraging strategies in order to obtain adequate amounts of sodium in their diet. However, even though sodium hunger may be recognized by the animal, it is debatable whether generalist feeders are genetically programmed to recognize foods that will correct this specific deficiency. Thus an element of learning is involved in identifying the sodium source.

The contemporary view of nutritional wisdom discounts the possibility that animals are genetically programmed to directly taste or smell nutrients. Instead, this view recognizes that animals learn about the foods they ingest. Thus the selection of a diet occurs through learned associations that are modified by past experience. Learned associations are acquired through the pairing of the food's oro-sensory cues (smell, flavour, texture, temperature) with post-ingestive feedback from the body. This more complex view also takes into account that learned associations can be further modified by physiological status and environmental conditions such as the presence of **conspecifics**.

O

Observational learning

Observational learning is a subcategory of **social learning**. Many animals can learn by observing the behaviour of another animal, or the consequences of the other animal's actions (Heyes and Galef, 1996). One of the most widely studied examples is feeding among domestic chickens. When chickens eat a distasteful food, they shake their heads, gape and wipe their beaks, i.e. the disgust reaction. Chicks observing others giving this reaction after pecking at coloured beads coated with a distasteful substance subsequently avoid these colours. However, adult hens do not avoid coloured food that another hen has found to be distasteful (Sherwin *et al.*, 2002), indicating that observational learning might be more important for juvenile animals in some circumstances. Observer hens seeing demonstrator hens not feeding, feeding on normal food or feeding on highly palatable food did not change the amount of food they ate; however, there was a positive correlation between the pecking rate of the demonstrators and the proportion of food of the demonstrated colour eaten by the respective observers. There was also an interaction with the colour of the food: the effect of observing a hen eating highly palatable food induced the birds to eat more red food, which they otherwise avoided.

Natural populations of black rats also show observational learning. Young rats learn from their mothers how to strip seeds efficiently from cones. Observational learning can sometimes be as simple as directing another animal's attention to an area of the environment (**local enhancement**), or a feature of the environment (**stimulus enhancement**). Careful laboratory studies have addressed the question of whether more complex observational learning occurs, e.g. whether animals can imitate opening an 'artificial fruit' (Whiten and Custance, 1996) or whether parrots can imitate human movements (Moore, 1996).

Observer effect

Observer effect refers to the possible changes that the act of observing will have on the phenomenon being observed. For example, animals may be aware when human observers are present and may consequently alter their behaviour when being observed. This may lead to inaccurate representations of the animals' normal behaviour patterns.

Odour

Odours are received through both the nose, the chemosensitive trigeminal pathway, and the **vomeronasal organ**. The vomeronasal organ is particularly involved in receiving **pheromones** that control **aggressive behaviour** and the oestrous cycle of many mammalian species. Some authors dismiss the need for distinction between odours and pheromones, and some refer to the latter as social odours.

Pheromones are a specialized group of chemical attractants produced by animals to stimulate other animals, especially in intra-species social **communication**, but also some interspecies communication. They are secreted by interdigital, infraorbital, inguinal, sebaceous and salivary glands and are particularly concentrated in the perineal region. They are also present in milk, urine and the other body secretions, including sweat. In ungulates there are many different types, including alcohols, diols, alkanes, ethers, diethers, ketones, primary amines and aromatic alkanes. The oestrous pheromones are mainly released from the body surface, particularly the hindquarters and genital region, rather than in urine, faeces or vaginal mucus.

For example, cows in oestrous display spend much time sniffing and licking each others' ano-vaginal areas. Bulls respond to odours produced by **teaser** bulls even more than to pheromones identified in the blood of oestrous cows. Bulls can also detect a change in the pheromonal secretions of cows up to 4 days before the day of **oestrus**. On the day of oestrus the main olfactory system of nasal detection is operative, and the **flehmen** expression is not always used. The ability of bulls to predict oestrus in cows relates to their tendency in wild herds to 'guard' cows as oestrus approaches. In domestic herds in which there is no competition between bulls this does not occur. To test for cows' odours, bulls sample the urine of potential oestrous cows and mark the ground with pheromones by rubbing their head and neck on the ground. **Homosexual** cow relationships appear to be stimulated by sniffing and licking, particularly in the perineal regions.

Other animals, such as dogs, cats and rats, can also detect the oestrous odours of cows, but they are not able to distinguish pre-oestrous odours from those produced at other stages in the cycle in the way that bulls can.

P.440

Pheromones are also used to convey **fear**, and cattle respond to the pheromones produced by **conspecifics** that have been mistreated, with increased cortisol production and a reluctance to engage in activities where they might expose themselves to perceived dangers, such as **feeding**. Fear pheromones are present in the blood and also in other body fluids, such as urine.

(CJCP)

Oestrogen(s)

This is a group of sex steroid hormones found in females and males; it is secreted by the ovarian follicular cells during the oestrous cycle and from the Sertoli cells in the testis. The **adrenal gland** cortex secretes a precursor (dehydroepiandrosterone) that may be converted into oestradiol by tissues. These hormones are responsible for the secondary sex characteristics (e.g. mammary gland development, cornification of the vagina in preparation for mating) and are closely involved in a feedback loop to the **pituitary gland** for the regulation of the ovarian cycle (**see: Oestrus**), eventually leading to ovulation and the formation of a corpus luteum.

Oestrogens also affect the behaviour of animals preparing the females for mating and acceptance of the male(s) at the time of oestrus (a period of 'desire'), through behaviours such as standing still for the male to mount (most species) as well as flicking the tail to one side (bitches) or **lordosis** (rabbits). In male animals, the role of oestrogens may be in synchronizing sperm development, whereas the administration of oestrogens to males (for tumours of the Sertoli cells in dogs) leads them to develop female characteristics.

Oestrus

Mammalian females show a cyclical reproductive pattern, with the majority of species exhibiting distinct periods of increased sexual activity (**see: Sexual behaviour**) termed oestrus, or heat (also estrus, while oestrous/estrous is used in the

adjectival form). Equivalent sexual periods in other taxonomic groups are generally not referred to as oestrus. The term oestrus is derived from the Greek word *oistros*, meaning gadfly, or frenzy, as it was thought that gadflies around cattle drove them into a frenzy of activity and noise like that shown by cows in heat. The primates are an exception among the mammals, showing little or no overt behavioural cycle, and reproductive activity is regulated by a menstrual cycle.

There are two important behavioural components to the oestrus cycle, exhibited as increases in both receptivity and in **proceptivity**. Females are receptive to males during the oestrous period in that they will allow mounting and intromission; they frequently adopt a specific stance characterized by immobility, arching of the back and deflection of the tail - in rodents this is termed **lordosis**, but many other mammals exhibit species-specific variations of this behaviour.

As well as a passive increase in receptivity towards males, females also show proceptive behaviours during oestrus, behaviour patterns designed to advertise the female's reproductive status in order to attract males and to initiate copulation. This often involves an increase in general affiliative behaviour (**see: Affiliation**), with an increase in proximity accompanied by other solicitous responses such as butting or rubbing against males.

Oestrous females in herd situations may also seek to drive away other females or even to disrupt copulation, particularly where a strong **social hierarchy** exists and dominant females ensure their precedence over subordinates. In addition to behavioural signals, females may utilize other auditory, visual or olfactory cues to advertise their oestrous state, such as: (i) calling; (ii) adopting specific postures; and (iii) colour changes to draw attention to their sexual parts, through either the release of **pheromones** from specific glands or by an increased urination rate. During the anoestrous period, females may show contraindications, actively avoiding males, striking out or showing other aggressive responses, vocalizing and moving away if approached by males.

The cyclical behaviour patterns observed during oestrus are coordinated with the reproductive cycles, which regulate ovarian events, particularly follicular development and oogenesis culminating in ovulation, and uterine preparation for fertilization and the receipt and implantation of the embryo. This coordination is dependent on the hypothalamic-pituitary-ovarian endocrine axis. The **hypothalamus** secretes **gonadotropin-releasing hormone (GnRH)**, which regulates the release of the pituitary gonadotropic hormones, **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**, which, in turn, indirectly lead to production of the ovarian steroids **oestrogen** and **progesterone**.

The oestrous phase of the cycle is predominantly under the control of oestrogen produced by the growing and maturing ovarian (Graafian) follicles. The earliest events of oogenesis and folliculogenesis are independent of pituitary hormones; however, the later stages of follicular recruitment, establishment of dominance, completion of meiotic metaphase I and ovulation are all critically dependent on FSH and LH levels. Growing follicles actively produce oestrogen, which acts as an important regulator for the oestrous behaviour patterns. Raised levels of oestrogen also prepare the female tract for sperm transport to the site of fertilization in the oviduct.

Following ovulation, the formation of a corpus luteum producing progesterone results in dioestrous behaviour patterns (sexual quiescence). The expression of proceptive and receptive behaviour patterns by females during the oestrous period helps to ensure that mating will take place at an appropriate time during the reproductive cycle. In species where spontaneous ovulation occurs unrelated to copulatory behaviour (unlike the induced ovulators, such as the domestic cat), ovulated eggs have a limited fertile lifespan within the oviduct, during which they must be fertilized by the male's sperm before becoming atretic. Expression of oestrus ensures that males and females are drawn together at the right point of the cycle to maximize the chances of fertilization occurring.

The oestrous cycle is an endogenous cycle exhibited by mammalian females, but its expression may be entrained by environmental cues - principally by light, but temperature and nutritional plane may also affect the cycle, although both of these tend to be closely correlated with light levels. The environmental effects of light are regulated via the pineal gland, which secretes the hormone melatonin. Melatonin secretion is inhibited by impulses from the optic nerve, in turn initiated by light falling on the retina, and is increased during periods of darkness. Varying melatonin levels affect pituitary gonadotropin release in different ways, according to the

P.441

species. Species sensitive to these environmental cues are termed seasonally polyoestrous, as they show repeated oestrous cycles until mating results in pregnancy, but only during certain periods of the year, while at other times they exhibit no oestrous behaviour and are termed seasonally anoestrous.

The seasonal timing of oestrous behaviour and response to melatonin is closely linked with the **gestation** period of different species so that offspring can be produced - usually in late spring or early summer, when conditions are advantageous to the young and they have a maximal growth and development period before the onset of more rigorous winter conditions. Hence

sheep and goats, which have a 6-month gestation period, are short-day breeders with oestrous behaviour occurring in response to declining day length in autumn and early winter, while horses are termed long-day breeders as they respond to increasing day length in the spring, reflecting their longer 11-month gestation period. Other species such as pigs are relatively unaffected by day length and will cycle at all times of the year, while others still may only show single, isolated oestrous periods with prolonged anoestrous phases in between, and these are termed monoestrous - an example being the wolf.

As well as responding to environmental cues, the timing and incidence of oestrus may also be influenced by the presence or absence of male animals. In a range of species the introduction of a male has been shown to advance the appearance of oestrus (Whitten effect) and to cause synchronization of oestrus in groups of females (Bruce effect). In a number of cases these effects have been demonstrated by exposing females to male secretions such as urine, saliva or other specific scent gland products.

Familiarity with the overt signs of oestrus has traditionally been important in livestock husbandry, allowing for efficient and safe mating of livestock species - for example, the observation of 'bulling' in cattle, female-female mounting behaviour, as an indicator that cows are in heat and ready to be introduced to the bull. Similarly, sows may be tested by applying pressure to their backs in order to determine whether they will stand for a boar. A range of semi-automated systems has been devised for oestrus detection so, for example, general activity levels increase in the oestrous period and pedometer systems set to automatically flag increased movement levels in cattle have been used to indicate oestrous cows within a herd. Pressure sensors have also been used to indicate when female mounting has occurred, or vasectomized males may be used to mark oestrous females when they mount.

In horse **breeding**, mares are traditionally exposed to a **teaser** stallion, whose job is to elicit signs of oestrous behaviour. Teasing may be performed by the covering stallion but, with more valuable stallions covering large numbers of mares, frequently a separate teaser stallion that has high **libido**, but is easily and safely managed, may be used to test the mares before they are covered (mated) by the breeding stallion, which is thus protected from the adverse responses of an anoestrous mare.

Increased availability of on-farm ultrasound scanning has allowed the extent of ovarian follicular development to be monitored directly in many cases without having to consider the rather more indirect behaviour signs of oestrus. However, observation of the correct behavioural responses that females exhibit during the oestrous period remains one of the best indicators of an animal's readiness to mate.

(MRC)

Olfaction

Most higher animals are able detect **odours** from inanimate and animate objects and utilize the information to modify their reproductive, ingestive or **social behaviour**. However, despite the existence of two nostrils, there is only limited evidence that mammals can localize odours efficiently. The detection of odours has been studied less than the other primary senses, but they are clearly of major significance, especially in animals such as cattle, which evolved as prey, that needed durable, covert signalling. Odours are used particularly in intra-species **communication**, where they synchronize **reproduction**, act as territorial markers and **signal** the presence of predators. Other possible odour signals include **aggression**, **hunger** and **anxiety**.

The first stage in odour perception is the odour entering the oronasal cavity by the mouth or nasal orifices. This chemically stimulates olfactory receptor **neuron(e)s** (ORNs), which terminate in cilia that are bathed in mucus. Acting in parallel is the chemosensitive trigeminal pathway, the neurons of which also terminate in the nasal cavity. Neurons in this pathway are activated by many of the same chemical stimuli that activate ORNs, but the trigeminal system is particularly specialized in detecting irritants.

The third major site of odour reception, in addition to the olfactory and nasal trigeminal free nerve endings, is the **vomeronasal organ**, which is not well developed in adult humans but is well developed in most mammalian species. It is situated in the roof of the mouth and consists of blind, tubular diverticula, lined with olfactory epithelium. Vomeronasal organ neurons are not ciliated but end in microvilli, which are particularly sensitive to low-volatile compounds in water. These are common in urine and are used for social and sexual communication, including the detection of oestrous females by the male. The reception of odours by the vomeronasal organ is also used for **reinforcement** and the maintenance of sexual interest during copulation.

Air is sampled via the buccal cavity and the nose, although the nostrils are partially closed by the curling of the lip in this behaviour. The characteristic **flehmen** expression, whereby the head is directed upwards with the mouth ajar, the tongue flat and the upper lips curled back, is thought to aid odour sampling in ruminants by allowing air to be inhaled so that it passes over the roof of the mouth. Flehmen is also believed to act for appeasement, being the antithesis of the threat display. Different forms of flehmen exist in other species, for example in the cat, where it resembles a facial grimace.

Territorial animals use **scent marking** extensively, particularly **ungulates** - the dikdik builds dung heaps and rubs its forehead on them to increase its scent. The pronghorn urinates before defecating to amplify the scent. Deer have tarsal glands and also sudoriferous scent glands in their forehead that they use for marking territory. Sheep are reputed to be able to track **conspecifics** in mountain territory, presumably by detecting tarsal gland secretions. Cattle are not territorial in this way and defecate more or less at random. However, bulls do paw and dig their horns into the ground, then throw the soil over their withers, which may amplify their scent. In deer, smell is also

P.442

important in **diet selection**. Although specific tests have not been conducted with cattle, it is likely that smell is unimportant for cattle **grazing** a uniform pasture with a limited range of botanical species, because repeated exposure to odour stimuli reduces sensitivity as the receptor sites become locked up.

In humans smell perception may be impaired, not so much by the sensory apparatus as by the lack of detailed information processing by the **brain**. Much of this is due to lack of training, because we focus on developing other sensory abilities, but human perception is also less acute. Humans can actually identify their own odours, synchronize menstrual cycles using body odours and recognize their mothers' odour at 5 days of age.

Many animals are highly sensitive to the odours of potential predators, and increase their investigatory behaviour, spending more time sniffing the air and in cautious movement. Most domesticated animals are far more sensitive to chemical odours than are humans. For example, the chemical sensitivity of cattle ranges from being able to detect very weak solutions of sodium salts (10^{-4} M solutions of sodium bicarbonate) up to large hydrocarbon molecules and steroids. In comparison with man, a microsmatic animal, ungulates are macrosmatic. Humans can usually detect an intensity difference about one-third that of the actual intensity, whereas rodents can detect a difference of one-twenty-fifth.

Ontogeny

Ontogeny refers to the development of a behaviour pattern in an individual through the integration of learned and innate aspects of the behaviour, and is one of four groups that **Niko Tinbergen** used to divide the study of behaviour (**see: Tinbergen's four questions**). Ontogeny can also refer to the history and development of an organism from the fertilized egg to maturity.

Open-field test

The open-field test involves placing an experimental animal into a large, unfamiliar arena in order to measure its behavioural responses. The open-field test was originally developed by Hall (1941) as a method of measuring fearfulness in rats, and subsequently used by Hall and Broadhurst (Broadhurst, 1975) as a basis for performing divergent selection for defecation (Maudsley reactive and non-reactive rats). A large number of responses to threatening and potentially threatening stimuli have been measured in later experiments comparing the Maudsley strains. Because many behavioural differences indicate a higher level of fearfulness in the reactive strain and a lower level of fearfulness in the non-reactive strain, these studies provide some support for the hypothesis that open-field defecation in rats reflects fearfulness and that fearfulness is partly under genetic control. However, a number of studies using the open-field test for measuring fearfulness

have produced very ambiguous results. Caution should therefore be used when interpreting open-field behaviour, and alternative tests are often preferable.

In addition to its use for laboratory rodents, the open-field has also been used in modified forms on a large number of other species, including cattle, goats, sheep, poultry, foxes, pigs and rabbits. The aim of the experimenter is often to quantify the balance between an animal's anxiety-related and exploratory tendencies as a measure of fearfulness, or simply to quantify the animal's level of activity shown in response to this novel test situation. Interpretation of open-field behaviour in terms of activity in a novel environment has some empirical support, but there is often little support for interpretation of open-field behaviour in terms of fearfulness.

There are several **motivations** and **emotions** that may influence an animal's behaviour in the open field, and limited possibilities for controlling the direction of their effects on an animal's behaviour. The most obvious emotion that may be observed is novelty-induced **anxiety**, which results in **avoidance behaviour**, arousal and observation of the surroundings. Curiosity is another fundamental emotion elicited by novelty, and leads to approach, investigation and exploratory responses.

A major problem with the open-field, as opposed to the **approach test**, is that it is difficult to define approach (reflecting curiosity) and avoidance (reflecting anxiety) in the open field. Whereas some herbivores and ungulates may prefer open spaces, many other species may be attracted to the relative safety that the walls of an open-field test arena represent. However, when measuring relative levels of approach to and avoidance of the central areas of an open-field arena, one normally presupposes that the apparatus is large enough for the animal to distinguish between open and protected areas. One also presupposes that the species does in fact perceive open space as aversive. In cases where the animal has no aversion to open space, or the open-field is too small, responses often give little information besides indicating the animal's activity in a novel environment.

In addition to the above, socially reared animals may be highly motivated to reinstate social contact with **conspecifics** when tested singly in the open field. This may be observed as high levels of activity aimed at escaping. **Fear** of humans in aversively handled animals, or attraction to humans in handreared animals, may also influence their behaviour in the open field. Whereas livestock treated poorly by **stockpersons** may avoid the handler and flee into the centre of the open field, animals handled gently may be distressed by the absence of the handler and seek to reinstate contact. In some experiments, blood sampling is performed prior to testing. Although such aversive handling may strongly affect subsequent behaviour during testing, this has seldom been investigated systematically. Whereas fearful rats may defecate and show signs of behavioural suppression when exposed to the open field, this may not apply to other species, which may behave quite differently when exposed to a novel enclosure.

Spaciotemporal measures that may be recorded in the open-field include total distance walked (locomotive activity) and **locomotion** in the centre relative to locomotion at the periphery of the apparatus. However, locomotion in the periphery may be difficult to interpret, as discussed above. Total locomotion is also difficult to interpret in terms of

P.443

anxiety, because changes in activity may have several causes. Changes in activity may reflect **disinhibition** of locomotion following a period of deprivation in a small home cage or pen, or reflect the animal's **coping style** during forced exposure to **novelty**. Locomotive activity is also difficult to interpret because immobility (the lack of locomotion) is frequently interpreted as indicating increased anxiety in a novel environment. This latter interpretation is based on the fact that immobility is often associated with increased avoidance of potentially dangerous objects.

Species-specific ethological measures recorded in the open field may include different postures, defecation, **vocalization**, rearing on the hind feet, sniffing or rubbing components of the room and apparent attempts to escape. Sometimes, physiological measures such as **glucocorticoid** secretion and **heart rate** are also recorded. When several measures are simultaneously recorded in the open-field test, scores generated by principal component analysis may aid in interpreting behaviour.

To summarize, interpretation of open-field behaviour in terms of anxiety or fearfulness (emotionality or emotional reactivity) is often unclear. The open field has seldom been subjected to satisfactory validation (but see Gray, 1987; Salvatierra and Arce, 2001), and some attempts at validating it have failed (Andersen *et al.*, 2000). Because of this, it is probably best to avoid using the open-field test for measuring these emotional reactions or **personality/temperament** traits. Despite its general weaknesses as a test of anxiety or fearfulness, the open-field test may, however, be useful for assessing the level of activity displayed in a novel enclosure.

Operant response

An operant response is one that can be modified by its consequences, an element of which may be referred to as an operant. A free operant response is an operant behaviour that can occur at any time, because it is not dependent on any time or resource-limiting event. Running may be considered a free operant response, whereas hunting depends on the availability of prey and so is not a free operant response. In an experimental situation evaluating operant conditioning (**see: Conditioning - types of; Instrumental conditioning**) it is usually preferable to use free operant responses as the substrate for the experiment. The level at which an operant response occurs prior to any significant reinforcement is referred to as the operant level, and is the baseline against which an assessment of the effects of potential reinforcement or punishment can be assessed.

(DSM)

Operant test

An operant test is an experiment in which the delivery of a resource or event is contingent on an animal's behaviour (operant response). Because approach and avoidance are operant responses, even simple **choice tests** are, strictly speaking, operant tests. However, common usage of the term 'operant tests' excludes choice tests. An operant test may be used to investigate an animal's **motivation** and preference. The subject may be required to perform a response, or refrain from performing a response, in order to either obtain a **positive reinforcer** or avoid an aversive (**see: Aversion and aversives; Reinforcement - types of**). It is usual for only one reinforcer to be contingent upon responding at a given time (unlike choice tests). Reinforcers or aversives may be compared retrospectively by reference to a common measure of responding. Another typical feature of an operant test is that the response is specifically trained and sometimes manipulated to vary the cost of access to a reinforcer, although some procedures remain difficult to classify (**see also: Economics of behaviour** for an explanation of some of the terms used in this entry).

Research questions addressed by operant tests

The research questions addressed by operant tests can be broadly divided into four categories:

(A) To ascertain whether an animal is motivated to obtain or avoid a resource or event (**see: Choice test**). These work on the principle that an animal will learn to perform, or refrain from performing, an operant response to obtain a resource or event that is rewarding, or to avoid an event that is aversive.

(B) To ascertain whether an animal has a preference among alternative reinforcers (**see: Choice test**). These operate on the principle that the more strongly motivated an animal is to obtain or avoid a reinforcer, the greater its response (e.g. intensity, frequency, rate) should be. There are two approaches:

(i) in the first, used mainly to compare negative reinforcers, subjects respond to obtain/avoid the alternative reinforcers sequentially. The validity of this procedure is limited when comparing positive reinforcers. (ii) The second approach, used to compare positive reinforcers, is a hybrid operant × choice test, in which reinforcers are made available concurrently. In practice though, simple choice tests are most frequently used to ascertain whether a preference exists.

(C) To measure the strength of an animal's motivation for a reinforcer (**see: Choice test**). These are often based upon those designed to ascertain whether a preference exists. However, for positive reinforcers, an important difference is that the reinforcer of interest is compared to one for which the animal has an independent motivation. Strength of preference (between the reinforcer of interest and an alternative) can be assessed if the animal has free access to an alternative during the test; strength of motivation is assessed if the animal has no access to an alternative during the test. These tests work on the principle that the stronger an animal's motivation to interact with one reinforcer compared to another, the greater its response should be for one compared to the other, so long as they satisfy the same motivation. If this is not the case, a

P.444

second approach may be used in which the degree to which an animal is prepared to give up or work for one reinforcer is compared to another.

(D) To ascertain whether the strength of an animal's motivation for a reinforcer, or the strength of its preference between two reinforcers, is altered by changes in its internal or external environment. For example, we might ask: 'is feeding motivation in restricted-fed animals reduced by bulking out the diet with roughage?', 'does nesting motivation increase as oviposition time approaches?', or 'is handling rendered less aversive by previous experience?' These are similar to those designed to ascertain whether a preference exists (B) or to measure the strength of motivation or preference (C). The only difference is that a single reinforcer is evaluated and the procedure is repeated before and after changes in the subject's internal or external environment.

Specific procedures

Listed below are procedures that have been used by ethologists, together with the type of research questions that might be addressed using the given approach, using the letters (A) to (D) from above:

1. Response acquisition (A). An attempt is made to train the subject to perform an operant response, either to obtain the hypothesized reinforcer, or to avoid or terminate exposure to it. Limitations include the fact that motivation may be confounded with the degree of compatibility between response and reinforcer (salience), because animals have a biological propensity to associate certain behaviours with certain stimuli or outcomes. For example, it may be easier for a chicken to learn to scratch for access to a dust bath than to peck for one. However, this can be avoided by either training a response that resembles natural aversive or appetitive behaviour for the motivation in question or training several different responses.

2. Response frequency, or number of reinforcements earned (also called the 'y-intercept of the demand curve') (B, C, D). The subject is required to respond on a fixed ratio schedule (**see: Reinforcement - types of**) during a session of fixed duration to obtain or avoid something. This procedure is carried out for each reinforcer of interest, or comparator, in turn. The greater number of responses performed or reinforcements obtained is used to determine a stronger motivation for that outcome (e.g. number of times an animal accesses food versus a companion). However, when comparing positive reinforcers that satisfy different motivations, motivational strength is confounded with the quantity or interaction time required to reach satiation.

3. Passive avoidance - dual schedules, with multiple reinforcements per session (A, B, C, D). The subject is trained to respond on two ratio or interval schedules, either concurrently or alternately, for access to a standard positive reinforcer (e.g. food). Then, in a series of treatments, response X is followed by exposure to an aversive of interest (e.g. the type of vibration associated with **transport**) plus the standard positive reinforcer (e.g. food), while response Y is followed by access to the standard positive reinforcer only. A decline in the magnitude of response X, relative to response Y, reflects the level of motivation to avoid the aversive.

4. Passive avoidance - single schedule, with multiple reinforcements per session; aversive versus positive comparator (C). The subject is required to respond on a single ratio or interval schedule during a set time for access to the comparator.

Responding on this schedule is followed by exposure to the aversive of interest plus the comparator. If the response magnitude declines substantially, then motivation to avoid the aversive is comparable to motivation to obtain the comparator.

5. Runway test/chamber entry test - latency to approach/leave (A, B, C, D). The subject may initially be trained to move between location X (e.g. a chamber or one end of a runway), containing no reinforcer, and one or more adjoining locations Y (e.g. an adjoining chamber, the other end of a runway or the arms of a Y-maze), each containing either a reinforcer of interest, a comparator, or no reinforcer (control). Then, in a series of treatments, the subject is placed in location X (for latency to enter) or Y (for latency to leave) and allowed to move at will. If the latency to enter/leave location Y when it contains the hypothesized reinforcer is less than the latency to enter/leave this location when it contains no reinforcer, then the subject is motivated to obtain/avoid the reinforcer; a smaller latency to enter/leave location Y in one treatment than in another indicates a stronger motivation. However, it is important to note if there is a ceiling effect on approach/withdrawal rate.

6. Runway test/chamber entry test - passive avoidance (A, B, C, D). The subject is trained to move along a runway or enter a chamber to reach a standard positive reinforcer (e.g. food). Then, in a series of treatments, traversing the runway or chamber entry is followed by exposure to the aversive of interest or a comparator, plus the standard positive reinforcer. In a common variant, subjects are forced to traverse a runway without any positive incentive. (However, this is not an operant test according to common usage, because subjects do not learn to perform a response.) An increased latency to enter/traverse the chamber/runway in the test indicates that a motivation to avoid the hypothesized reinforcer exists and a greater latency in one treatment than in another indicates that motivation to avoid the reinforcer in the former is stronger.

7. Runway test/chamber entry test - passive avoidance versus positive comparator (C). The subject is required to traverse a runway or enter a chamber to reach the comparator. Traversing the runway or entering the chamber is then followed by exposure to the aversive of interest plus the comparator. For example, this has been used to investigate the perception of noxious gases used in the euthanasia of mink. If latency to enter/traverse the chamber/runway declines substantially, then motivation to avoid the aversive is comparable to motivation to obtain the comparator. If the subject refuses to enter/traverse the chamber/runway, then motivation to avoid the reinforcer of interest exceeds motivation to obtain the comparator.

8. Cross point of two concurrent demand curves (B) (see also: Economics of behaviour). The subject is required to respond during a series of concurrent fixed ratio schedules to obtain a fixed quantity of reinforcer X on one schedule and a fixed quantity of reinforcer Y on the other. The schedule (relative 'price') of reinforcer Y is steadily increased, while the schedule for reinforcer X is held constant or decreased. The cross point is the price at which the curves overlap, i.e. the price at which demands for the two reinforcers are equal. From

P.445

this the relative motivation for X compared to Y can be assessed.

9. Matching law (B). The subject is required to respond on a series of concurrent variable-interval schedules to obtain different reinforcers. The session ends either after a fixed period of time or when a given number of reinforcements have been earned. The schedules are changed once a criterion for stable responding has been met and the process repeated. According to the matching law, the relative number of responses performed on the two schedules (P_X/P_Y) and the relative amount of time spent responding on the two schedules (T_X/T_Y) both increase as the relative rate of reinforcement on the two schedules (r_X/r_Y) increases. From this, the relative strength of motivation for the two alternative reinforcers can be calculated. This approach has been used, for example, to assess the strength of preference for different rooting substrates by pigs.

10. Work rate (B, C, D). In a series of treatments, the subject is required to respond by pushing on a door or operating a switch until a fixed amount of work (force \times time) has been accumulated, to obtain a single exposure to either a reinforcer of interest or a comparator, for example access to a nestbox or food for chickens. More rapid completion of the task or greater average effort in one treatment over another indicates that motivation to obtain the reinforcer in the former is stronger.

11. Break point (B, C, D). In a series of treatments, the subject is required to respond on a single progressive ratio schedule (an ascending series of fixed ratio schedules, increased after every reinforcement), to obtain a reinforcer of interest or a comparator. The session ends when the subject has ceased responding for a specified period. A greater number of responses performed, or a higher schedule reached, in one treatment compared to another indicates that the motivation to obtain the

reinforcer in the former is stronger; for example, this has been used to assess the effect of food deprivation on sows. When comparing positive reinforcers that satisfy different motivations, motivational strength is confounded with the quantity/interaction time required to reach satiation. This may be ameliorated by ensuring that the size of each reward is small.

12. Highest price paid (also called reservation price) (B, C, D). In a series of treatments, the subject is required to respond on an ascending series of fixed ratio schedules, or on a schedule with increasing response difficulty or aversiveness ('prices'), to obtain either a reinforcer of interest or a comparator. The schedule is gradually increased until the subject fails to earn the reinforcer. The reservation price is the highest price reached, and this was used to determine the value of group housing to sows (Kirkden and Pajor, 2006). It estimates motivation for a single access to a reinforcer, or for the quantity obtained in the time allowed. A higher schedule reached indicates that the motivation to obtain a single access to the reinforcer is stronger in the given circumstances.

13. Price elasticity of demand or slope of the demand curve (B, C, D). This involves a similar methodology to that used to determine highest price paid, except that the reinforcer is made freely available for a set time (rather than being a single event). The schedule is gradually increased, sometimes until the number of rewards earned ('demand') falls to zero. Demand is plotted against price to obtain a demand curve. If the absolute slope of this curve is less in one treatment compared to another, then motivation to obtain the reinforcer in the former is stronger. Alternatively, if the slope of the curve for the reinforcer of interest is not significantly different from zero, or if its price elasticity of demand is less than 1 ('inelastic demand'), then motivation for this reinforcer is strong. Empirical findings suggest that, for two reasons, it is not valid to infer a strong motivation from inelastic demand. First, price elasticity of demand is influenced by procedural variables such as reward size and response type and for a given reinforcer it can vary widely between studies. Secondly, practically every reinforcer that has been evaluated in an operant test exhibits price inelastic demand. This is likely to be an artefact of the methodology of operant tests. Therefore a comparator should be used to assess the relative, not absolute, strength of motivation.

14. P_{\max} (B, C, D). This procedure is a variant on the price elasticity of demand approach and is used when there are nonlinear demand curves. Demand is measured at a series of prices, in the same way as in the price elasticity of demand approach. P_{\max} is defined as the price at which the price elasticity of demand is equal to 1. At this price, the subject performs a maximal number of responses ('work') for the reinforcer. A greater P_{\max} in one treatment compared to another indicates that motivation to obtain the reinforcer in the former is stronger. This approach has been used, for example, to help to determine preferred stocking density by laboratory rats.

15. Consumer surplus (also called travel cost consumer surplus) (B, C, D). Demand is measured at a series of prices, in the same way as in the price elasticity of demand approach (13). Price is plotted against demand. The consumer surplus estimates motivation for access to a specific quantity of a reinforcer (e.g. to a single reinforcement during the course of a day, the first ten reinforcements or a satiating quantity), or motivation for access after a particular prior level of consumption (e.g. the tenth reinforcement of the day). It corresponds to an area under the curve, bounded by two points on the demand axis. For example: the consumer surplus for the first reinforcement is an area between demand = 0 and demand = 1 (equal to the reservation price); the consumer surplus of a satiating quantity is the entire area under the curve. A greater consumer surplus in one treatment than in another indicates that motivation to obtain a specified quantity of the reinforcer in the former is stronger. Although claims for using this parameter have been made in the animal welfare literature (e.g. Mason *et al.*, 2001), this has not been done in practice, because the surplus can only be measured if the price of each commodity is raised relative to the price of others rather than all raised together.

Some limitations affecting several of the procedures, which should be considered

i. The five general limitations listed for choice tests (i.e. motivation depends on context experience, availability of alternatives and other cues and does not reveal what is good for welfare in the long run) also apply to all operant testing procedures, with the exception that an open economy is integral to the matching law approach (9).

ii. When alternative positive reinforcers are evaluated sequentially, preference may be masked if a need to satisfy the motivation overrides a preference for how to satisfy it.

iii. When comparing positive reinforcers that satisfy different motivations, with access to multiple reinforcements per session, reinforcer magnitude (quantity/duration) may be controlled either by the experimenter or by the subject, but

either approach can be problematic. If the experimenter has control, restriction/interruption of bouts may devalue some reinforcers to an extent that depends on the motivation in question. However, if the subject has control and cost is manipulated, cost and reinforcer use may not co-vary (Mason *et al.*, 1998). However, for some reinforcers, reward magnitude may be controlled by the experimenter without devaluing them. For other reinforcers, the subject may be given control, but if cost and resource use do not co-vary, the approach will not yield valid measures of motivation, although it may be possible to usefully determine the highest price paid.

iv. When comparing positive reinforcers that satisfy different motivations or negative reinforcers that involve different mental states, motivational strength may be confounded with the degree of compatibility between response and reinforcer, because animals have a biological propensity to associate certain behaviours with certain stimuli/outcomes. This problem can be solved by training responses that are not specific to one of the motivations being measured.

v. When using consumer demand approaches in which income is constant, price changes have income effects (Kirkden *et al.*, 2003). The problem can be ameliorated by either ensuring that income is high; or evaluating a small quantity of the reinforcer of interest where this is possible.

vi. When comparing positive reinforcers that satisfy different motivations, there are several important considerations: motivational strength depends on deprivation level, so when a single measure is extracted from a demand curve, the measure is of limited practical value. Also, motivational strength is confounded by the rate at which subjects satiate for a resource as they earn more. Finally, motivational strength is also confounded with the quantity consumed or interaction time when price is low. However, in this latter instance it is possible to factor out this quantity or time in the analysis.

Operational definition

An operational definition of something defines it in terms of how it can be recognized, rather than its intrinsic properties. For example, **stress** might theoretically be defined in terms of an individual's cortisol level, and thus cortisol levels might be used to compare the stress resulting from different procedures. However, this approach does not tell us about the nature of stress, beyond its measurement. Thus operational definitions allow scientific investigation at one level, but caution is required in their extrapolation when it comes to defining the nature of a potentially subjective phenomenon that

is defined in this way - i.e. in the example above, the nature of stress when defined by cortisol level is not clear, and it cannot be assumed to be directly related to suffering.

Opioid

Any chemical (natural or synthetic) that has an effect like the **narcotic** (sensation-numbing) alkaloids derived from opium, such as morphine, may be referred to as an opioid. This includes natural **brain** chemicals, such as the **endorphins** and **enkephalins**. Strictly speaking the term opiate should be applied only to the natural chemical derivatives of opium and not to the synthetic drugs like heroin and hydrocodone that are related to these compounds.

(DSM)

Optimal fitness

The term 'optimal fitness' may be considered a misnomer for either of the terms 'maximal fitness' (**see: Fitness; Inclusive fitness**) or 'optimal strategy for fitness' (**see: Optimal strategy**), because natural selection favours strategies that maximize, not optimize, fitness, i.e. a strategy may be optimized to maximize fitness (**see: Optimality**).

(PE)

Optimal foraging

Foraging means 'searching for food'. Within behavioural ecology, the study of **foraging behaviour** was combined very early on with **optimality** theory to make models that predict the behaviour of animals. This connection between optimality theory and foraging behaviour is so strong that it is used to describe almost all studies of foraging, and hence the term 'optimal foraging'.

There are two classical models of optimal foraging: the marginal value theorem and the prey-choice model (Stephens and Krebs, 1986).

The marginal value theorem

The marginal value model predicts the behaviour of an animal that is searching for patchily distributed food. The food in the patches is depleted as the animal forages in them. The question the model answers is: how long should the animal stay in one patch before changing to another patch? The most important assumptions that are made are:

- The animal has perfect knowledge of the content of a patch once it visits it.
- The animal does not know how far it is to the next patch.
- The cost of travelling from one patch to the next is the same as foraging in the patch.

What the model maximizes is the intake rate of the animal. These assumptions might seem to make the model totally unrealistic. Experiments have, however, shown that the predictions of the model fit surprisingly well, at least qualitatively. The two main predictions from the model are that you should stay longer in better than average patches and, as the mean travel time increases, the time spent in a patch - the giving up time - should increase.

Picking mushrooms is a good example of the kind of situation that the model makes predictions about. Mushrooms are not distributed evenly in the landscape, but in patches, and we usually cannot see the next patch and therefore do not know exactly how far it is to the next patch. We also want to pick as many mushrooms as possible, as fast as possible.

The prey-choice theory

The second classical model is the prey-choice model. It models a situation in which the animal encounters prey, with two different types of prey of differing benefits (in the model, energy contents) and costs (in the model, handling times). The assumptions of the model are:

- The prey types are encountered sequentially and randomly (the probability of encountering a prey is independent of when the prey has previously been encountered).
- Searching and handling of prey are mutually exclusive activities.
- The energy content, cost and encounter rate are fixed.
- Encounter without attack is instantaneous and incurs no cost.
- The animal has complete information concerning the encounter rates, costs and benefits of the model.

The strongest and most controversial prediction from the model is that the bad prey type (i.e. the one with the lower energy content/handling time value) should either always be eaten or never be eaten. This is irrespective of the encounter rate of the two prey types. This all-or-none **preference** is not generally found in animals - they instead show partial preferences (Krebs *et al.*, 1977). An example of the type of situation modelled is a fish that stays in a fixed position in a stream encountering different types of prey floating by.

Both of these models are rate-maximizing models, i.e. what is maximized is intake over time. This has very strong similarities with models of learning, and many situations investigated by experimental psychologists can also be understood in terms of optimal foraging.

The assumption of complete information is often criticized. Sampling alternative food sources, and acquiring information concerning their availability and handling, is obviously an important part of the foraging behaviour of many species. This has been extensively studied in, e.g. bumblebees, which have one flower species on which they specialize and one or two alternative species that are continually sampled (Heinrich, 1979). Attempts have also been made to model the relation between exploration and exploitation in foraging situations (McNamara, 1982; Inglis *et al.*, 2001).

There are also models of optimal foraging that take other aspects into account. In models of risk-sensitive foraging, for example, the variability of the food sources is considered. What is maximized in these models is not the rate of intake but the probability of intake rate staying over a certain threshold (in effect, maximizing the likelihood of survival; Caraco *et al.*, 1980). The digestibility and nutritional content of the prey/food are other aspects that are often modelled.

Optimal strategy

Organisms have to allocate their limited resources between competing life history traits. The suite of behavioural, physiological and developmental trade-offs that results in the greatest propagation of the relevant genes (i.e. evolutionary pay-off) can be considered the optimal strategy. Ethologists have used the concept to analyse the day-to-day activities of animals, such as **foraging behaviour**. The logic here is that individuals that optimize components of their behaviour will leave the most descendents (i.e. will have maximized their **fitness**). Although this concept has been applied with great success in so much as aspects of behaviour can be predicted very accurately given knowledge about the costs and benefits of engaging in an activity, there are good theoretical grounds as to why studies of behavioural optimization should be interpreted with caution. For example, the optimal strategy may depend on what other strategies are being employed within the population (**see: Game theory**).

Stamp-Dawkins, M. (1995) *Unravelling Animal Behaviour*, 2nd edn. Longman, London.

Optimality

Optimization, as applied to animal behaviour, is the behavioural repertoire that yields the greatest benefit to cost differential. It is built on the premise that animals perform a suite of behaviours in order to survive and reproduce, and those that perform these behaviours efficiently leave the most surviving offspring, who in-turn inherit these characteristics

P.448

(**see: Optimal strategy**). Thus, over evolutionary time, the behaviours are predicted to become more and more efficient and, ultimately, optimal. The basic concept - that natural selection favours those individuals that behave optimally - has enabled behavioural ecologists to make very precise predictions about how animals will behave under particular ecological conditions, given knowledge of the costs and benefits associated with the particular activity.

In essence, the theory proposes that individual reproductive success is maximized through the optimization of day-to-day activities, such as foraging. However, the link between short-term optimization and lifetime reproduction success is not straightforward. For example, a less-than-optimal forager that is more alert to predators may leave more surviving offspring than the optimal forager that is unaware of the approach of danger (**see: Optimal foraging**). This also highlights another problem with the theory: it is difficult to categorize behaviours into discrete, independent units. For example, while collecting food, a bird may be classed as foraging, but it is also likely to be watching out for predators and/or potential mates, thus it is difficult to justify the categorization of this behaviour as foraging. Optimality theory has also been criticized on the grounds that animals are adapted to past environments, not the present, and that phylogenetic inertia will often mean that animals are less than optimal. There are also methodological difficulties: to 'prove' that animals are behaving optimally, there needs to be a close fit between observed and predicted results, yet the scientific method is primarily based on the refuting of a null hypothesis. Thus, the demonstration of a statistically non-significant difference between what is observed and what is predicted might arise from poor scientific methodology.

The above criticisms have led some to reject optimality theory. However, the fact remains that the theory does enable behavioural ecologists to make very accurate predictions about how animals will behave under certain circumstances. It is of no surprise that some of the best examples of optimality theory involve cases in which short-term gains are almost certainly linked to long-term reproductive success. For example, a parent bird that optimizes the rate of delivery of food to a nest full of chicks is likely to maximize its reproductive success. In a similar vein, male dung flies that optimize the rate at which they fertilize the ova of females will sire the most offspring. Thus, the fact that animals appear to behave optimally under some circumstances would indicate that natural selection has operated in the past to produce very efficient (optimal) behaviours under certain circumstances.

Orang-utan

Meaning 'forest people' in Malay, orang-utans are the largest arboreal mammal inhabiting the rainforests in Asia. There are two extant species of orang-utans, Bornean (*Pongo pygmaeus*) and Sumatran (*Pongo abelii*), found on the islands of Borneo and Sumatra, respectively, and both are at risk of **extinction**. Characterized by their reddish coat and long arms, orang-utans are primarily frugivores, eating other items opportunistically. As adults, orang-utans are sexually dimorphic, with males being larger and possessing enormous cheekpads. They are members of the **great apes**, but are unique in their semisolitary behaviour and **noyau social organization**.

(LAN)

See also: Endangered species

Orchidectomy

Orchidectomy is the removal of the male **gonad**, also known as **castration**, though that term can also apply to removal of the ovaries (ovariectomy) of females. This is a surgical procedure usually carried out in immature animals (**see: Mutilation**). It is done to make animals more tractable and easier to handle, to stop them being aggressive and to stop them mating when animals are kept in mixed-sex groups. In male cats, benefits may be claimed for the cats themselves, as their roaming and fighting can lead to them having recurrent fights and infections, and hence a reduced **quality of life**.

It is normally performed with an anaesthetic in animals with a high economic value (dogs, cats and horses), but not in young farmed animals such as piglets, lambs and calves. However, recent research has shown that young animals are also able to feel **pain**, and methods to provide some form of **analgesia** and/or **anaesthesia** are being researched and developed for farm animal species.

(DBM)

Organic farming

Organic farming takes an holistic approach to farming and its principles are based upon the maintenance of the natural equilibrium that exists between animals, plants and the soil. Emphasis is given to the concept of naturalness (**telos**) within the definition of animal **welfare** of many organic systems. In 2005 the International Federation of Organic Agricultural Movements (IFOAM) outlined the ethical principles for organic farming. These are the principles of **health**, **ecology**, fairness and care. However, official standards for organic certification vary between different areas. Organic farming works with and supports natural ecological systems, and practices that may cause an imbalance between and within these systems are avoided, including high stocking densities, artificial fertilizers, chemical pest control and genetically modified organisms.

Claims over the production of a high-quality product is one of organic farming's main principles, and feed rations are designed to maintain animal health rather than optimize production. In support of this, minimum **slaughter** ages are set for each type of animal to prevent excessive **growth rates**, and overproduction is further avoided by limiting stocking densities to a farm's ability to recycle manure and to produce most of its own feed requirements.

Maintaining animal health is claimed to be a high priority for organic systems, and pharmaceutical therapeutics (drugs) may be used only as a last resort if alternative products have little or no effect on a **disease**. Though sick animals must be treated promptly, it is the prevention of disease that is one of the basic principles of organic farming. Breeds or strains of animals that have a naturally high resistance to disease are selected, and are fed nutritionally balanced feed rations that further promote their ability to ward off disease.

The health and welfare of stock are also given high priority in **housing** systems, and environmental diseases are controlled

by cleanliness and appropriate stocking densities. The design of housing must allow for free movement, access to food and water and must have sufficient **lying** area, which should also be littered with a natural substance such as straw.

Additionally, housing systems should also cater for **behavioural needs** at different stages of life and allow for the expression of natural behaviours such as socializing with **conspecifics**, rooting behaviour and avoidance of dung.

Castration of males is permitted to avoid tainted meat, but other systematic **mutilation** of body parts, such as tail-docking (see: **Docking - tail**), teeth trimming and **dehorning**, is not permitted unless these actions can be justified in terms of health and safety.

Orientation response

The orientation response is the behaviour shown by an individual when a novel, unpredicted or potentially threatening **stimulus** is presented to it. The response is associated with increased attention towards the stimulus to allow its evaluation. At the same time, there is often an increase in **arousal** and activation of physiological systems in preparation for the 'fight or flight' response, depending on the outcome of this evaluation. Repeat presentation of the stimulus may result in **habituation**, as evidenced by a loss of the orientation response, and so it may be used to investigate this form of learning.

Ostensive definition

An ostensive definition defines something by way of examples. Implicit within the use of ostensive definitions is an assumption that this information can be generalized or used to create a reliable concept. Thus a stressor might be defined ostensively as something like a painful procedure, a scary event or something that makes the individual feel sad. In this case, the definition is likely to lead to the assumption that stressors are detrimental to **welfare**, and this may or may not be the intention of the individual providing this definition. Thus the **reliability** and **validity** of the definition as a form of communication are dependent on the quality of the examples offered, as well as the level of understanding of the receiver of the information. Ostensive definitions are often used when it is difficult to precisely define or interpret the nature of the subject of interest.

(DSM)

Ostrich

The ostrich (*Struthio camelus*) is the world's largest living bird, standing around 2 m tall and weighing 100-150 kg. Native to Africa, four subspecies, generally geographically separated, have been recognized largely on the basis of the colour of the skin and wing and tail feathers. Males have black body feathers, unlike the brown-grey body feathers of the female; both genders have white (or brown) primary wing and tail feathers. In sexually active males, the skin on the face, abdomen and legs flushes red. Young chicks are mottled brown, white and black, moulting out to brown-grey plumage in juveniles. The feathers are symmetrical, lacking interlocking barbs typical of other birds. The adult ostrich is a neotenus bird retaining chick-like characteristics (e.g. large eyes and soft, downy feathers) when becoming sexually mature.

The ostrich exhibits a flightless, cursorial lifestyle in open savannah, scrub and desert areas. Although capable of running at speeds of 40 km/h, this is usually only a response to a threat. The main diet of the bird is formed by vegetation, which is processed by an alimentary tract characterized by a large, expandable proventriculus, a large, muscular gizzard (which

relies on swallowed stones to assist in grinding food) and a relatively small intestine compared with the very long colon. Digestion is assisted by microbial fermentation in large, paired caeca and proximal colon, and the short-chain fatty acids produced are absorbed in the distal colon. Micturition and defecation are separate events.

The ostrich is a herbivore feeding on a wide variety of plants according to the prevailing flora. Green annual forbs and grasses are preferred, although leaves, flowers and fruit from succulent plants will also be consumed. Selection of food items is by sight and the beak is used to strip the leaves. Up to one-third of the bird's time is spent **feeding**, a behaviour that occurs in bouts, often while walking, interspersed with periods of vigilance.

Breeding is relatively opportunistic and generally reliant on environmental conditions (especially rainfall). Male ostriches establish and defend territories around which the females wander before settling on one male with which to establish a nest. Courtship involves an elaborate display by the male, including a booming call and showing the female potential nest sites. Mating can occur outside of established pairs, and many females will lay some of their eggs in other nests. Egg laying takes place every 48 h and the clutch of roughly ten eggs can take 3 weeks to complete. The number of eggs in a nest can be much higher because of egg dumping by other females, but, once incubation is established, many of these eggs are pushed out (although it is unclear how the incubating female recognizes her own eggs).

The egg is the largest laid by any living bird (average of 1500 g, measuring 15 × 12 cm) and has a gross composition similar to that of the domestic fowl egg. Incubation takes 42 days and is continuous with the male sitting at night and the female sitting by day. Hatched chicks are ~30 cm tall and fully **precocial**, leaving the nest after 24-48 h to follow their parents in looking for food and water. Typically, groups of chicks form crèches looked after by one pair of birds until they are well-grown juveniles (**see: Cooperation**). Adult height is reached by 12 months of age and sexual maturity is at 2-3 years.

For many centuries ostriches were hunted for their feathers, which were used as human adornment. During the 19th century it became apparent that **slaughter** of wild ostriches was not sustainable, and in South Africa some birds were brought into **captivity**. Nevertheless, the ostrich remains threatened in much of its natural range. Captive breeding was fully established in the late 19th century by development of an artificial incubator, although captive adult birds were used to

P.450

foster-rear most chicks. Farming was largely based around providing grazing on irrigated lucerne (alfalfa) supplemented by maize. Breeding birds were either kept in 'free-range' large groups or as pairs in small enclosures. **Captive breeding programmes** were also established to develop a bird more suited to a farming environment and for the regular plucking of mature feathers from living birds. To a large extent, this farming system still applies in South Africa.

Farming brought a rapid expansion of the worldwide market for feathers, and vast fortunes were made, particularly by farmers around Oudtshoorn, South Africa, which became (and remains) a major centre for ostrich farming. At this time ostriches were exported to North America, Europe and Australia, where farming operations were also established. In the early 20th century demand for feathers fell dramatically. By the 1930s only remnant farming operations remained in South Africa, and ostrich had disappeared from other parts of the world. By the middle of the century, a marketing cooperative was established in South Africa that developed the market for leather tanned from the skin of ostrich slaughtered at around 12-14 months. Characterized by patches of raised quills, ostrich leather was marketed as a high-quality, highvalue product. The leather market led to a renaissance of ostrich farming in South Africa. More recently, the product range was extended by sale of the high-quality leg meat, often erroneously marketed as being low in cholesterol.

International sanctions against South Africa during the 1980s produced a shortage of ostrich hides, and ostrich farming became more attractive for other parts of the world. Aggressive marketing caused an extremely rapid spread of ostrich farming in North America, which led to an increasing awareness around the world. By the mid-1990s ostrich farming operations were established in Israel, Australia, Europe and other African countries.

Outside of South Africa, ostrich farming has been attempted in a wide range of climates and geographical conditions, although the farms are usually small in size. Often breeding birds are kept in 'trios' (one male with two females) in small enclosures. Eggs are artificially incubated and the chicks are intensively reared. Common problems have involved maintaining the health of birds, getting good **egg production**, fertility, hatchability, and poor survivability and **growth rates** of chicks. Commercial production and marketing of the products has been a major restriction to development of an ostrich industry to match that of South Africa. As a result, many farming operations in North America, Europe and Australasia closed down by the end of the 1990s. The few remaining ostrich farms in the UK are small-scale and service a local market they have developed.

Despite this decline in interest, ostrich farming continues to capture the imagination of farmers in many developing countries. At the start of the 21st century the market for ostrich products has recovered to a large extent. Ostrich farming remains strong within South Africa but, although more widespread geographically, elsewhere its commercial significance is limited.

Overshadowing

If two potential conditional stimuli are repeatedly presented simultaneously in a classical conditioning procedure, it is possible that only one of them will be associated with the conditional response. This is because more intense or relevant stimuli may overshadow less intense or relevant ones. At a practical level, it is particularly important to be aware of overshadowing when training animals, because much training is done with verbal commands, but these may be overshadowed by the unintentional visual cues provided by the trainer at the same time, such as hand gestures or body posture. Thus the animal may initially appear to have learned to respond to the command, when in fact it has not.

Oxytocin

Oxytocin is a nonapeptide (consisting of nine amino acids). It acts systemically as a hormone and within the **central nervous system** as a neurotransmitter or neuromodulator. The molecular structure is the same in all mammals, and the amino acid sequence of the oxytocin-like nonapeptide in birds and reptiles differs by only one or two amino acids.

Oxytocin is produced in the supraoptic and paraventricular nuclei of the **hypothalamus** and is secreted from the posterior **pituitary gland**. Oxytocin is also found in other locations because of projections of **neuron(e)s** from the paraventricular nuclei to sites in the **brain**, the brain stem and the spinal cord. The release into the bloodstream is highly pulsatile. The nature and frequency of pulses vary according to the species, sex and reproductive condition, but the pulsatility is an important functional aspect. Effects are often produced on pulsatile release that cannot be obtained via general increase in basal level, or only at much higher concentrations. **Opioids** are of importance in the regulation of oxytocin, both at the level of the posterior pituitary and within the hypothalamus.

Oxytocin is well known for its involvement in **reproduction**, but it also seems to have general anti-**stress** properties. The types of behaviour that are induced are dependent on the prevalent steroid pattern and on the environmental cues.

Parturition

Parturition is associated with a cascade of hormonal changes, including the release of plasma oxytocin. Oxytocin causes uterine contractions when the uterus is responsive to it (due to various hormonal events, oxytocin receptors are up-regulated prior to parturition). Experiments on rodents and pigs have shown that environmental disturbances, i.e. movement to a less attractive location early in parturition, can disrupt parturition through an opioid-mediated inhibition of oxytocin secretion. When an opioid inhibitor was given prior to movement, parturition proceeded irrespective of movement and, when oxytocin was administered after movement, parturition was reinstated. Oxytocin, or an artificial version of it, is often used to promote parturition in domestic animals and humans. In the chicken, the hypophyseal nonapeptides arginine vasotocin and mesotocin (which is the avian form of oxytocin) are responsible for oviposition.

Lactation

During **lactation**, oxytocin is involved in the nursing process. Oxytocin is released into the blood in response to sensory

manipulation of the teats. Via the circulation, it reaches the mammary glands, where it causes milk ejection by contracting

the myoepithelial cells. In oxytocin-knockout mice, transfer of milk failed but the deficit could be repaired by administration of oxytocin. Milk ejection in dairy cows has been studied in detail because the efficiency of milk letdown has great practical and economic importance. Natural suckling by a calf has been found to cause greater oxytocin release compared with machine **milking**. This is probably related to the greater sensory input from manual stimulation or suckling by a calf than from the milking machine. Manual pre-stimulation of the teats before attaching a milking machine, as well as hand-milking during the entire milking process, enhances the levels of oxytocin. The reflex can become associated with environmental stimuli, so that oxytocin is released in anticipation of the sensory stimulation. Hence, the sound of the milking machine may evoke letdown in cows, and women may respond to the cry of a hungry baby in the same way, because of prior associations between these sights and sounds and nipple stimulation.

Mother-offspring bonding

In several species, oxytocin has been shown to promote mother-offspring **bonding**. In rats, the oxytocin released within the brain at parturition is involved in stimulating the rapid onset of **maternal behaviours** acting on up-regulated oxytocin receptors. Similar actions of oxytocin have been demonstrated in sheep, in which the central release of oxytocin is triggered by stimulation of the uterine cervix and vagina. In sows, oxytocin seems to be involved in timing of maternal responsiveness to piglets, i.e. to the change from being relatively responsive during the initial phase of parturition to being passive and non-responsive during parturition and the early postparturient period - which allows piglets to access the udder and reduces the risk of piglet crushing - to a later increase in responsiveness. In humans and non-human primates, correlation studies suggest that a link between oxytocin and maternal behaviour also exists in these species.

Sexual behaviour

Oxytocin is involved in **sexual behaviour**, but there is large interspecies variation in the distribution of oxytocin receptors in the brain. This may be one of the reasons why species vary in the role of oxytocin in sexual behaviour. For example, it plays a significant role in inducing sexual behaviour in rats (e.g. penile erection in the male and **lordosis** in the female), but not in mice. In general, in relation to mating, oxytocin is thought to reduce aggressiveness between individuals and to facilitate receptive behaviour, sexual arousal, orgasm and sexual satiety.

Social behaviour and memory

Oxytocin also has more general effects on the **social behaviour** and **memory** of several species. In monogamous female voles, it enhances selective social behaviours and the formation of pair bonding. Unmated females develop partner **preferences** when given oxytocin centrally or peripherally, providing this is done in a manner in which the pulsatility of oxytocin is mimicked. Data on mice have also indicated that oxytocin is involved in social memory, i.e. the development of social familiarity. In contrast, other studies implicated oxytocin as an amnestic peptide. Apparently an intracerebral oxytocin stimulus may enhance forgetting, whereas systemic oxytocin may enforce memory.

Anti-stress system

Oxytocin seems to be implicated in a general anti-stress system. In conscious rats, massage-like stroking of the abdomen is followed by increased oxytocin levels. At the same time, there is a lowering of **blood pressure** and release of vagally regulated gastrointestinal hormones, indicating a shift from sympathetic to parasympathetic autonomic dominance. The massage seems to sedate the rats, as reflected by reduced locomotor behaviour, and they have prolonged withdrawal latency to heat and mechanical stimuli. Peripherally administered oxytocin produced similar acute effects. The effects of a 5-day treatment with oxytocin were pronounced and longlasting (e.g. decreased blood pressure for 10 days in males and 20 days in females) and, when rat pups were treated immediately after birth, these effects were lifelong.

An anti-stress system involving oxytocin (or mesotocin, which is the avian equivalent) does not seem to exist in birds. In broiler cockerels, stepping and wing flapping increased dose-dependently with intracerebral oxytocin administration, but **preening** decreased. The experimenters interpreted the results as suggestive of a role for oxytocin in inducing a state of **arousal** in chickens that resembles **fear/anxiety**. This seems to contrast with the effects found in mammals.

P

Paedomorphosis

Paedomorphosis describes the evolutionary retention of juvenile characteristics into adulthood, i.e. it is the phenotypic outcome of the exclusion or reduction of some ancestral developmental stages during the **ontogeny** of an individual. A classic example of paedomorphosis is seen in the axolotl, (*Ambystoma mexicanum*), which is a form of salamander that, as an adult, has the external gills that are characteristic of the young of other species of salamander, but which are normally replaced by lungs in these related species as the animal matures. The opposite to paedomorphosis is peramorphosis, which reflects the outcome of the inclusion of all relevant normal developmental processes seen in the ancestor as only part of the related ontogeny of the feature of an individual - i.e. the animal appears to develop in certain ways beyond the stages seen as the norm in close relatives or its presumptive ancestors. The exaggeration of certain traits as a result of **sexual selection** and gigantism within a taxon, may arise as a result of peramorphosis, i.e. the animal may continue to develop these features beyond the normal limit of adulthood seen in related species - for example, the extensive antlers of some species of deer.

Such phylogenetic changes in the relative timing and rate of developmental processes are collectively referred to as **heterochrony**. Historically, within the field of applied animal behaviour, emphasis has been given to the consideration of the importance of paedomorphosis arising as a result of **domestication**. For example, juvenification may be associated with greater (but still limited) developmental adaptability in response to the man-made environment and a reduced risk from **aggression**, which are favourable traits; however, many domestic species appear to show a mix of paedomorphic and peramorphic change. The occurrence of such changes in these species can also be used as a basis for criticism of assessments of the welfare impact of domestic management regimes (**see: Intensification of animal production**), which are based on simple analogy with the wild type in similar circumstances. Some texts appear to confuse the term 'paedomorphosis' (a phenotypic outcome) with 'neoteny' (a slowing of development), which describes one of several mechanisms leading to paedomorphosis (see heterochrony for a more extensive description of the mechanisms underpinning this phenomenon).

Pain

Pain, in humans, is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. A similar definition of pain also applies to animals: pain is an **aversive** sensory and emotional experience by the animal in response to damage or a threat to the integrity of its tissues. In animals, as in humans, pain has both a physiological sensory and a psychological or emotional component. Physiological components are the conscious experiences of pain resulting from activated nociceptors (from the Latin *nocere*, 'to hurt') following tissue damage, while subjective contents are an unpleasant sensory and emotional experience that occurs with actual or threatening tissue damage.

However, pain in animals is relatively difficult to recognize and assess, since the exact nature of the emotional component remains uncertain, and an animal is unable to report the qualitative and quantitative dimensions of the sensory (pain) and emotional experience. The level of pain experienced can be affected by the maturation of the nervous system and by other factors such as **memory**.

Nociception that results in a feeling of pain will result in altered behaviour. Within a few milliseconds there may be a very rapid withdrawal motor reflex - for example, when touching something very hot. This is mediated through synapses between the sensory nerve and the relevant motor nerves in the spinal cord with the first-order **neuron(e)**. However, after that time, any motor movement or altered behaviour is most likely to be voluntary, e.g. to run away and escape, to limp, to vocalize. These behaviours are a result of the pain that is felt in the cerebral cortex, and the motor response will depend on the area affected.

Pain is classified as being acute or chronic, according to its characteristics. Acute pain is related to nociceptor activation following **injury**, and ends when the stimulus ends. The chronic pain phase is defined as an intense pain lasting weeks or months beyond the expected injury healing time, or as pain involving an alteration in the nervous system that is capable of maintaining a painful state after the stimulus is removed and the injury is healed. Chronic pain is characterized by an abnormally lowered pain threshold, so that normal, innocuous stimuli elicit pain (allodynia). The experience of pain upon nociceptor stimulation is more intense than normal (hyperalgesia).

Following tissue inflammation and injury, specific nociceptors and/or 'silent' nociceptors are elicited, from where arisen nerve signals are transferred to the surface layers (lamina I and II) and the neck (lamina V) of the dorsal horn of the spinal cord by lightly myelinated (A δ) and unmyelinated (C) fibres; the signals then ascend to the thalamus through the spinothalamic tract, mediating the discriminative component of pain sensation and,

P.454

together with the spinoreticular tract, produce the emotional-affective component of pain sensation.

Based on the 'gate control theory' of pain, the nociceptive system undergoes modulation at the dorsal horn level of the spinal cord. A pathological activity of sensitized nociceptors leads to plastic alterations at both peripheral and central levels following an injury or **inflammation**. These changes increase peripheral sensitization and central hyperexcitability, such as abnormal sensation in the somatosensory system (neuropathic pain), and reduce activities of pain inhibitory systems, such as the functions of the periaqueductal grey matter, Raphe magnus nucleus and dorsal horn (laminae I and II) in the spinal cord, leading to a decrease in the pain threshold and hyperalgesia (increase in the intensity of pain), as well as allodynia (pain elicited via activation of normally non-painful AB fibres by an innocuous stimulus such as touch).

Palatability

Palatability refers to the hedonic quality of orosensory stimuli or the experienced pleasantness of a **taste**. Palatability may be indexed by changes in observable behaviours such as taste reactivity responses, which have been categorized in a number of species. The term is also used to refer to food properties that promote ingestion, or the immediate effect of a food on ingestion.

(SuH)

Parasite

A parasite is an organism living within or on the body of another species (i.e. the host) and obtaining from the host food and/or protection. Parasitism is thus beneficial for the parasite and costly for the host. Parasites may spend their whole life on one host, or spend different developmental stages in hosts of different species. Their impact on animal welfare is

variable, being dependent on load and virulence, but particularly a cause for concern in organic farming systems, where the use of agents to control parasite loads is limited.

Parasitism

Parasitism, or parasitic symbiosis, can be defined as the symbiosis between animal host and infecting organism, whereby the latter has a perceived benefit and the animal host suffers detrimental effect or at least where the infecting organism lives at the expense of the animal host. The infectious organism is called the **parasite** and, based on the definition, can be a virus, bacterium, fungus, protozoan, helminth or arthropod. However, classic parasitology usually excludes viruses, bacteria and fungi, to be examined within the discipline of microbiology. It distinguishes between endoparasitism and ectoparasitism. Endoparasites are internal, and include the gut and blood parasites, while ectoparasites are mainly involved in cutaneous infestations. In some cases parasites themselves will contain parasites, i.e. hyperparasitism, for example the *Plasmodium* parasite within the *Anopheles* mosquito, or the *Dipylidium* tapeworm cyst within the *Ctenocephalides* flea larva.

The forms of parasitic coexistence are too numerous to cover in this context but, in reference to behaviour, parasites have been found to have unique abilities to influence animals' behaviour. To illustrate, some parasites affect the ability of their host to increase the chances of the host becoming prey and so enabling the completion of the parasite's lifecycle (*Leucochloridium* in snails). In other cases the parasite may manipulate the male host into diverting all its energy to nurturing the parasite, the former having been rendered sterile and displaying female behaviour. The parasites will now be treated as his brood to be protected (*Sacculina* in crabs).

(FLR)

Parasympathetic nervous system

The parasympathetic nervous system (PNS) arises in the craniosacral division of the spinal cord. The preganglionic nerve fibres originate from the motor nuclei of certain cranial nerves in the brain stem, as well as the 2nd to 4th sacral segments of the spinal cord. With few exceptions, most organs in the body of vertebrates are innervated by the PNS. The cranial nerves primarily innervate effectors within the head region (**see: Central nervous system**), such as salivary glands and papillary muscles. An exception to this is the vagus nerve (cranial nerve X), which innervates the heart and lungs, stomach and upper intestine and components of the urinary system. PNS nerve fibres (also called cholinergic fibres) terminate in varicosities, which are the sites of release of the neurotransmitters. The principal neurotransmitter in the PNS is **acetylcholine**, which is released at both the pre- and postganglionic levels. Acetylcholine is synthesized in the nerve terminals from choline and acetate, and stored in vesicles until it is released directly into the space surrounding the target cells. The activity of acetylcholine is efficiently inhibited by hydrolysis with an enzyme, acetyl cholinesterase, which is stored in the synaptic cell membranes.

The central function of the parasympathetic nervous system is to maintain metabolic equilibrium and replenish energy reserves when the body is in a state of rest, repair and restoration. The effects of dominant parasympathetic activity include decreased **heart rate**, increased visceral activity (e.g. digestion) and an overall decrease in metabolic rate, all of which contribute to the maintenance of **homeostasis**. Effects of activation within the PNS are much more refined than those exhibited by the **sympathetic nervous system** (SNS). There is no mass simultaneous activation of parasympathetic nerves, such as the general excitation seen in the SNS. Rather, individual nerves can be independently activated, which is facilitated by the typical 1:1 synaptic arrangement of pre- to postganglionic synapses. This configuration allows for very

specific activation of target effectors. For example, the vagus nerve can at any point in time function to regulate cardiac activity without having to exert any regulatory influence on the digestive system.

P.455

The PNS and SNS were traditionally viewed as exhibiting only coupled reciprocal control, where an increase in one branch lead to a decrease in the other. In many instances the branches do behave in a rigid bipolar or continuum fashion, with PNS activity at one end of the plane and SNS at the other. According to this model, the state of autonomic control at any point in time is characterized by a point on the continuum. In reality, however, the interrelationship between PNS and SNS activity is better represented by a bivariate model that encompasses reciprocal regulation as well as co-active and independent regulation. Co-active regulation, or coupled non-reciprocal control, describes positively correlated activity within the two branches. For instance, an increase in PNS activity is coupled with a similar increase in SNS activity. Independent, or uncoupled, activity occurs when a change in one branch is not accompanied by a change in the other branch.

There is increasing interest in the neural mediation of stress responses in farm animals, in particular in measuring activity within the subdivisions of the **autonomic nervous system**. In general, however, very little attention has been paid to the role that the PNS plays in instrumenting stress responses in any species. Of particular interest is the vagal nerve, which has both afferent and efferent capabilities. Two structures in the brainstem, the dorsal and ventral vagal complexes, are responsible for the regulation of PNS activity. The dorsal complex regulates parasympathetic activity beyond the level of the diaphragm, whereas the ventral complex controls activity above the diaphragm. Emerging research has shown that the ventral vagal complex is capable of expressing both inhibitory and excitatory control over cardiac activity, vocalizations and some respiratory functions. For instance, certain stressors can initiate PNS induced changes in heart and respiratory rate that do not require any activation of the sympathetic nervous system. The PNS, in particular the vagus, has also recently been identified as playing an important role in the neural regulation of the immune response. Afferent signals in the vagus nerve are involved in communicating with the CNS, via cholinergic anti-inflammatory pathways, to initiate early and rapid immune system responses to inflammation. This anti-inflammatory role is brought about by vagal inhibition of the release of TNF, HMGB1 and other pro-inflammatory cytokines through the activation of certain nicotinic receptors.

Parathyroid hormone

Parathyroid hormone is a peptide hormone active in calcium **homeostasis**. Release is stimulated by a decrease in extracellular calcium concentrations, from a number of small parathyroid glands adjacent to or embedded within the thyroid gland. Parathyroid hormone acts by stimulation of osteoclastic activity in promoting calcium release from bone, to both enhance calcium uptake in the intestine and reduce calcium excretion from the kidney.

(MRC)

Parental investment

Parental investment is 'investment by the parent in an individual offspring that increases the offspring's chances of surviving (and hence reproductive success) at the cost of the parent's ability to invest in other offspring' (Trivers, 1972). The evolutionary premise underlying parental investment is the concept of life history trade-offs, i.e. current reproductive effort diminishes residual reproductive value, or prospects for future reproduction, either by reduced survivorship or fertility. Parental investment among mammals is usually assessed in the context of maternal investment because of the energetic and time costs involved in **gestation** and **lactation**. Sex-biased parental investment is a process that involves differential allocation of resources and risks to producing and rearing daughters compared with sons, as a function of their anticipated reproductive output.

Sex-biased parental investment includes both differential partitioning of resources to sons or daughters, as well as facultative adjustment of secondary sex ratios. Sex-biased allocation of resources devoted to rearing offspring, rather than modifications in secondary sex ratio, is more likely among species with lengthy periods of infant dependency, while variation in sex ratio at conception is more likely among species that spend little time in rearing offspring. According to the Trivers-Willard model (Trivers and Willard, 1973), the difference in maternal timing of sex-biased investment is because sex-biased maternal investment is regulated by three life history requirements: (i) maternal condition is correlated with offspring condition at independence; (ii) offspring condition at independence is correlated with their condition as a reproductively mature individual; and (iii) adult condition has a direct impact on variation in reproductive output.

Since the concept of parental investment was formalized, and the conditions under which sex-biased investment were identified, over 1000 papers have been published that have attempted to determine the degree to which differential allocation of resources to sons and daughters has reproductive consequences for the mother. Antithetical conclusions have been derived from the published literature because of a number of brambles in the trail:

- Over a dozen ways to assess 'maternal condition', ranging from kidney fat index to body mass to chronological age to visual estimates, have been adopted by scientists.
- A minimum of three generations is required to test the model, because the maternal pay-off to sex-biased investment arises from offspring reproductive output.

P.456

- An unbiased secondary sex ratio or pattern of investment can be interpreted as either stochastic variation or support for the model, depending upon the relative costs and benefits of rearing daughters and sons.
- Both the production and rearing of progeny result from a myriad of complex factors, with animals residing in a variety of mating systems, so the search for a universal Holy Grail within labyrinthine biological systems creates nearly insurmountable odds.
- Ecological, demographic, social, and phylogenetic factors mould life history strategies, so female flexibility in response to local circumstances could increase fitness more than an inflexible strategy dependent only upon 'condition'.
- If females have evolved mechanisms to respond to local environmental perturbations, then adjustments in maternal investment over the short term could reflect either adaptive modifications or small sample size effects.
- Whether or not female mammals actually possess the ability to modify sex ratio at conception remains unknown.
- Females have evolved age-specific reproductive strategies, so the costs and benefits of adjusting maternal investment patterns might depend more upon chronological age or parity than upon body condition.

In sum, testing models of parental investment by collecting solid empirical data is extraordinarily difficult.

Evaluating parental investment presents an enormous academic challenge, but also provides a solid evolutionary basis for assessing trends and colony management programmes in zoological institutions. For a perspective on the topic, consider a few examples. In red **deer**, *Cervus elaphus*, variance in male reproductive success is a function of body size, which is strongly dependent upon levels of maternal expenditure. In bighorn **sheep**, *Ovis canadensis*, only a weak correlation connects maternal and lamb mass, with neonatal mass having an impact on adult male body mass and reproductive success. In rhesus **macaques**, *Macaca mulatta*, maternal mass accounted for about 8% of the variance in infant mass and about 2% of the variance in sons' progeny production. In neither African **elephants** nor Cape **buffalo** is sex ratio of progeny related to maternal condition, but heavier reindeer are more likely to have sons than are lighter reindeer.

One might reason that captivity could favour a male-biased sex ratio if body condition is enhanced under food provisioning and if maternal condition has a direct impact on the sex ratio of progeny. Suppose that life in a zoological institution resulted in increased body condition among females or in accelerated reproductive maturation. If animals have evolved physiological mechanisms to modify secondary sex ratio, and females in good condition tend to produce males, one might then obtain a male-biased sex ratio in captive settings. One might find that first-time mothers have more difficulty giving birth (if the advanced physiological state favouring reproduction is not accompanied by an increased rate of skeletal maturation). **Zoos** might also experience sampling error in sex ratio due to small sample sizes.

Confinement in zoological settings might be associated with increased **stress** levels that hinder reproductive output and thereby favour production of daughters, because female ability to partition extra resources into sons will be hampered by stress-related endocrine disruption. Comparative studies of both ungulates and primates in the wild and in captivity have not found any evidence that enhanced food availability influences secondary sex ratio. Furthermore, a survey of 66 mammalian species in North American zoos found little evidence that secondary sex ratio was male biased among polygynous species. In sum, although a logical argument can be made that maternal investment in mammals directly depends upon maternal condition, evidence that maternal condition impacts sex-biased investment is inconsistent and has been interpreted as both strong, as well as weak.

One might expect parental investment to be prominent in long-lived mammals where females need to allocate resources to dependent young that increase the likelihood of offspring survival, but that also hinder prospects for future reproduction by delaying subsequent conception. Females have probably evolved a context-dependent life history strategy whereby maternal effort is dictated not by sex of offspring, but by size of offspring, condition of mother and resource availability. Individuals have probably evolved an adaptive physiological flexibility that enables them to adjust maternal expenditure in offspring according to demographic, social and individual context. For example, among non-human primates, sexually monomorphic, dual-sex dispersing species, such as the whitehanded gibbon, *Hylobates lar*, should pursue different investment strategies from either sexually dimorphic, male dispersal species, such as savannah baboons, *Papio cynocephalus*, or sexually dimorphic, female dispersal species, such as **chimpanzees**, *Pan troglodytes*.

Since the phylogenetic history of mammals, birds, **reptiles**, amphibians and insects has produced a plethora of mechanisms for producing and rearing progeny, factors contributing to variation in secondary sex ratio or levels of maternal expenditure are not identical across taxa. Many alligators and turtles have temperature-dependent sex determination, whereby offspring sex is not due to sex chromosomes, but is a function of nest incubation temperature. Females can control birth sex ratios within litters by adjusting nest temperature. A number of insect species are haplodiploid, in which case the queen of the colony directly controls sex of offspring by either fertilizing or not fertilizing eggs. Among avian species, females have two different sex chromosomes, while males have a duplicate copy of the same sex chromosome, which is opposite to the case in mammals, so mechanisms of sex ratio adjustment at conception have to differ from those in mammals, where females are the homogametic sex.

The potential for sex-biased parental investment among females creates a golden opportunity for exploration among zoological institutions because of their long-term database. A productive research approach for the future is to identify factors that can, and do, modify parental investment among a variety of creatures under specific conditions. Uncovering proximate mechanisms that influence both secondary sex ratio and levels of maternal investment could enhance captive management programmes.

Parturition

Parturition is the act of birth (**see: Gestation**). This process may take a few hours to several days depending on the species, the number of pregnancies and whether the animal is polytocous, i.e. has several young at one time. It frequently occurs at night in some species, e.g. in rodents, but at any time in other species (cattle, sheep, dog). It comprises three stages: the first stage ends when the cervix is fully dilated due to hormonal changes (relaxin release) and uterine contractions push the **fetus** up against the closed cervix, gradually dilating it. The second stage involves the expulsion and delivery of the **fetus**. The third stage is when the placenta is expelled. Some animals like the sow, cat and dog and many rodents, have a strong desire to nest build at this time and will work hard to access nest-building materials, such as straw (sows) or pluck their own fur out (rabbits). Assistance may be required when difficulties threaten the welfare of the mother and offspring during parturition. Such difficulties are collectively termed dystocia. Caesarean section is an example of assisted parturition, where an incision is made through the abdominal and uterine walls in order to deliver the fetus.

(LW, DBM)

Paternal behaviour

Paternal behaviour patterns are associated with, or characteristic of, a father. Female reproductive success is limited by time and energy constraints and benefits from ensuring the survival of offspring. Commonly, the males of a species maximize their reproductive success by mating with multiple females (polygyny) and leaving them to care for the offspring. However, paternal behaviour is found in about 6% of species where two parents are necessary to provide for and defend the young, and is generally associated with monogamy (a single partnership between one parent of each sex). In mammals, much paternal behaviour shown is qualitatively similar to **maternal behaviour** with the exception of **lactation**, although there is often a quantitative difference in the behaviours expressed. In some species (e.g. sea horses), paternal behaviour involves greater investment and input to the rearing of young than that given by the mother, with the father taking on the more typical maternal role.

Pecking behaviour

The pecking behaviour of the domestic **chicken**, *Gallus gallus domesticus*, has been extensively researched, in large part because of the adverse welfare and economic impacts of damaging forms of pecking in this species. These include **feather pecking**, vent pecking and **cannibalism**. Pecking behaviours are often described by the substrate that is pecked; for example, feed pecking is distinguished from litter pecking. The morphology of the peck may also be used to describe it; for example, an aggressive peck is fast and directed at the head of another bird. The response of the recipient is also often

used in descriptions; for example, gentle feather pecks ignored by the recipient are sometimes distinguished from severe feather pecks, in which the recipient attempts to escape, on this basis. However, the behavioural motivation and function underlying the particular pecking behaviour may be obscured by such descriptions: pecks directed at feed may result in feed particle ingestion or be part of exploratory foraging and not result in any feed intake. The more commonly used descriptions of types of pecking behaviour used in the behaviour research literature are used here.

The ancestral species of the domestic fowl spends about 60% of its active day foraging for feed. Feral domestic fowl spend about 50% of the active day foraging. Feed pecks consist of the bird lunging at the food with an open beak, which then grasps the feed item. The head then withdraws before the item is swallowed. During foraging behaviour the bird pecks, pulls, tears and strikes substrates, pausing frequently to scratch alternatively with both feet and explore the scratched area with the beak. Newly hatched chicks have innate preferences to peck at small, spherical objects. These preferences are modified in the light of experience. The nutritional consequences of ingestion and **social learning** from **conspecifics** ensure that chicks peck less at inedible particles and more at edible particles. However, fowl will continue to peck at inedible substrates throughout life, to some extent. A **diurnal rhythm** of feeding develops by about 8 weeks of age, so that there are peaks in the morning and towards dusk. Feeding behaviour tends to be synchronized between individual hens due partly to 'social facilitation'.

Aggressive pecking commonly takes the form of a single, rapid and hard peck directed at the head of another bird. The recipient is often feeding, and the peck results in the cessation of feeding and an attempt to escape or show submission. The behaviour is rare before 3 weeks of age and becomes more common after 6 weeks. Fowl use these pecks, together with other aggressive behaviours, to establish a **dominance hierarchy** or 'pecking order'. Once formed, usually by about the tenth week of life, aggressive pecking becomes less frequent. Males perform more aggressive pecking than females. Increased competition for scarce resources can increase aggressive pecking. Aggressive pecking increases with group size up to about 100 birds, but thereafter increasing flock size seems to result in less aggressive behaviour. This is possibly

P.458

because hens in very large flocks are unable to distinguish between individuals, and hence adopt a strategy to avoid unnecessary agonistic interactions. Within some flocks, certain birds may attract more aggressive pecking than others. These 'pariah' birds have difficulty in feeding and suffer from poor body condition and low **egg production**.

Aggressive behaviour and aggressive pecking are often confused with feather pecking behaviour and cannibalism. Flocks in which cannibalism or feather pecking have occurred are frequently described as 'aggressive', and flocks without these problems as 'docile'. However, aggressive pecking can be distinguished from feather and vent pecking, in that it tends not to cause feather or tissue damage, tends to be associated with feeding and results in a behavioural response from the recipient. Feather pecking, on the other hand, does not seem to be related to competition for resources, is often ignored by the recipient unless it is severe and is unaffected by dominance position. Feather pecking may result in **feather** removal, feather damage or tissue damage.

Feather pecking involves a hen pecking at the plumage of another bird. The behaviour is common among laying chickens, both caged and those housed in alternative systems such as percheries or free-range. The behaviour also occurs in other species, such as **turkeys** raised for meat, or pheasants. It is much less common in broiler chickens. The behaviour has not been observed in the ancestral species of the modern chicken, the red jungle fowl (*Gallus gallus spadiceus*), when in its natural environment. Gentle feather pecking is defined in the behaviour literature as pecks to a conspecific's feathers which elicit little reaction in the recipient and do not involve feather pulling. Severe feather pecking is usually considered as either more forceful pecks with the recipient attempting to escape, or attempts at feather pulling which sometimes result in feather removal. The behaviour is important, since feather removal is likely to be painful and the resultant plumage damage reduces food conversion ratios, making flocks less economically efficient. Furthermore, measures taken to reduce this behaviour, such as **beak trimming**, also have an impact on chicken welfare and economics.

Feather pecking behaviour has been seen in chicks less than 2 weeks old. It is unclear whether this early pecking is under the control of the same behavioural systems as the more damaging pecking seen later in life. Peaks of feather pecking are observed at 4-6 weeks and 11-12 weeks of age, but the behaviour increases greatly after the onset of lay at around 18-20 weeks of age. This increase in damaging pecking may be associated with the increase in circulating gonadal hormones at this time. There are two main theories on the underlying motivational basis of feather-pecking behaviour. Both theories suggest that feather pecking behaviour results from the redirection of other forms of pecking behaviour. In the one case, feather pecking is considered to be a form of redirected foraging or ground-pecking behaviour. Various studies have shown a reciprocal relationship between foraging behaviour and feather pecking: improved quantity and quality of foraging opportunities reduces feather pecking. In the other case, feather pecking is said to result from chicks inappropriately

imprinting on feathers as a substrate during the development of **dust-bathing** behaviour. Such imprinting is less likely in the presence of a suitable litter substrate.

It is also possible that feather pecking is not derived from just one behavioural system. Feather pecking can 'spread' from bird to bird, which is one reason why it can be especially problematic in the large flocks housed in non-cage systems. There may be more than one mechanism responsible for this: there is evidence that damaged plumage can attract more pecking and that the behaviour may be socially transmitted when birds observe the behaviour in others.

Many factors increase the risk of feather pecking. Genetic influences are important: there are strain differences in propensity to feather peck and it is possible to selectively breed both for and against the behaviour. It is possible that selection for improved production may have inadvertently resulted in strains more likely to feather peck. This may be remedied by future selection for lower feather-pecking strains. Various factors are known to reduce the likelihood of feather pecking: (i) provision of good-quality litter in rearing and laying environments; (ii) dim lighting; (iii) feeding of an adequate diet; (iv) feeding mash rather than pellets; (v) the provision of perches in rearing and laying period; (vi) small group size; and (vii) lower stocking densities.

An epidemiological survey of alternatively housed UK flocks produced evidence that the following risk factors were associated with a greater likelihood of an outbreak of feather pecking: (i) less use of range on sunny days; (ii) frequent diet change; (iii) flock inspections by more than one person; (iv) the use of bell rather than nipple drinkers; and (v) the use of nestbox lighting. The causal relations of these risk factors with feather pecking are not yet ascertained. The same survey found that nearly 57% of responding farms reported outbreaks of feather pecking in their most recent flock.

Object pecking may be another form of redirected ground pecking. Hens will peck at inedible objects throughout their life, probably as a form of environmental exploration. They will **contra-freeload**, i.e. work for food by performing foraging pecks in the presence of a freely available food source. Object pecking is generally viewed as pecking at non-food, non-litter objects within the birds' environment, such as cage walls or furniture within pens such as perches. Increased object pecking has been noted experimentally in chickens undergoing fasts to mimic induced moulting. Object pecking has been reduced experimentally where hens have been encouraged to forage in litter enriched with grains. It is possible that there may be a relationship between feather pecking and object pecking.

Because of the interest in selectively breeding low-feather-pecking lines of laying hens, there is a requirement to find a suitable measure of the propensity of a bird to feather peck. Pecking at inanimate objects has been explored as one such measure, with equivocal results. In one experiment, birds identified as feather peckers were more likely to peck at a variety of objects, including buttons and feather bunches, than birds characterized as non-peckers. Birds from a high-featherpecking line pecked more at inanimate objects than those from a low-feather-pecking line in one experiment, whereas in another similar experiment no such relationship was found. In another study, no correlations were found between pecking at feather bunches and cannibalism. Inedible objects have also been used as a form of environmental enrichment in poultry, in an attempt to reduce injurious pecking behaviour. For

P.459

example, provision of white string elicits much exploratory activity, and there is some anecdotal evidence that it can reduce feather pecking in laying chickens. The provision of destructible objects, such as polystyrene blocks, may be most effective at reducing feather pecking.

Vent pecking is directed at the cloaca of conspecific birds, and usually results in tissue damage that can progress to evisceration and death, causing very high mortality in affected flocks. It is the commonest cause of cannibalism, when chickens peck and consume the flesh of their conspecifics. In the UK nearly 37% of farmers reported that the problem had occurred in their last flock. The behaviour often starts at the onset of lay. The reasons for its occurrence remain obscure, but the exposure of the cloacal mucosa after oviposition seems to be the stimulus that attracts pecking. The relationship between feather and vent pecking is unclear: many researchers consider them to be separate phenomena, whereas some suggest that vent pecking may develop from severe feather pecking. Providing perches during rearing may help prevent this vent pecking, by allowing birds escape from pecking flock mates, provided that perches are at a sufficient relative height. Perching within pecking distance of birds below may actually increase the risk of vent pecking. Risk factors for vent pecking identified in one UK survey include: (i) the use of nestbox lighting; (ii) changing the diet three or more times in lay; and (iii) the use of hanging bell drinkers.

Due to the tissue damage and painful death that can result from cannibalism, the welfare impact can be severe. Cannibalism frequently follows vent pecking, but may also be an indirect consequence of severe feather pecking which exposes and damages skin elsewhere on the body, such as the tail base. Experiments have shown that deliberately damaging birds' feathers increases the risk of cannibalistic attack. The phenomenon is affected by many of the same factors

that feather pecking is affected by. For example, providing a diet with adequate protein and a good-quality litter can reduce cannibalism. It is more common at higher light intensities, in birds being fed pelleted food rather than mash and in larger group sizes. Beak trimming reduces deaths from cannibalism.

As with feather pecking, outbreaks of cannibalism are unpredictable. Outbreaks can result in large mortality rates. Certain genetic strains of birds show more cannibalism than others. There is a possibility that cannibalistic birds have different individual characteristics than other birds: there is some evidence that they have larger body mass than others and are more active. It may be that a small number of such birds are responsible for starting outbreaks, and that other birds may then contribute secondarily. Following the first cannibalistic attack, hens in the group are more likely to perpetrate another attack. The mechanism for this is uncertain. Blood is known to be a potent stimulus for pecking in birds, but there is also some evidence that social learning of cannibalism can occur. The causal relations of these risk factors with vent pecking are not yet ascertained.

Perception

Perception is the process by which individuals register and evaluate information detected from the internal or external environment, consciously or unconsciously. For a **stimulus** to be perceived, information about it must first be detected and then undergo processing. An important aspect of perception is that the resulting representation of reality differs from reality itself; individuals sample information, and then form representations about the world and their situation in it. An individual's subjective representation of all perceived stimuli (i.e. its perceived world) is termed its '**umwelt**'.

It could be said that the senses provide the material for perception, while the processing system (usually a nervous system) provides the tools to shape it. The quality and quantity of stimuli that can be perceived depends on the individual's sensory apparatus, while the complexity of perception will depend on the individual's cognitive abilities and previous experiences.

Perception is a very broad term, being used to describe the process by which, for example, a plant *detects and orchestrates a response* to seasonal change, or at the other extreme, to distinguish between whether an animal *sentiently experiences* nociceptive stimuli as **pain** or merely responds behaviourally to the stimuli. The term therefore has a hierarchy of meanings depending on the organism in question and that organism's processing capabilities. In animals with a degree of behavioural flexibility, the perceptual process becomes much more complex, but it also retains some of the simpler aspects of perception, such as reflexes. Moreover, in humans and other sentient animals, the meaning of perception depends on what aspect of the process is under study. For example, in research fields focusing on sensory detection, the term is defined as

'information pick-up', while definitions within fields focusing on the later evaluation of information include perception as a mechanism for 'hypothesis generation'.

Information processing usually takes place via the nervous system, but even organisms that do not possess nervous systems, such as plants or *Paramecium* spp., are sometimes said to perceive stimuli in order to respond to them. Perception in these cases would refer to registering stimuli, presumably without **qualia**, leading to an inflexible evaluation of their biological relevance to the organism; these organisms can generally only respond in a hard-wired manner to the stimuli they register. Yet perception in these organisms can still differ from reality, leading to incorrect behavioural decisions. For example, a summer-flowering plant that uses temperature to induce flowering may flower too early if it experiences unusually warm springtime weather. This is a very broad meaning of perception, and is not usually relevant to animal behaviour or **welfare** studies.

P.460

In sentient or conscious animals, registering stimuli can produce **qualia**, which are the sensory **feelings** generated early on in the perceptual process. In these animals, the evaluation stage of perception can involve integrating information from different sensory modalities, categorizing and recognizing stimuli and determining their relevance. These processes may call upon learned information and memories, as well as genetically constrained, reflexive mechanisms. Some examples of this perceptual level come from work by Kendrick and colleagues showing that **neuron(e)s** in sheep's **brains** fire in response to specific categories of **conspecifics** and humans, whether the eliciting stimuli are olfactory or visual.

It is perception at this cognitive level that has been described as a process that generates hypotheses about reality - an individual develops moment-to-moment beliefs about the real world on the basis of the cues it detects and, through its behavioural responses, it might test those beliefs. For example, if walking through a tropical forest, we glance ahead and think we see a dangerous snake in our path, we might prepare ourselves for avoiding it, but also cautiously inspect it to get a better idea of what it really is. If on closer scrutiny we see that it is merely a piece of vine, the hypothesis that it was a snake is refuted, and we can continue along the path.

Perception can also be used as a term to differentiate between stimuli that are subconsciously processed versus those of which a human or animal is aware; perceived stimuli would be those that the individual is aware of, compared with all the other sensory information the individual would also have detected. In conscious or sentient animals, recognition of which stimuli are behaviourally relevant helps to direct attention toward those stimuli. Any irrelevant stimuli can then be ignored even if they have been detected by the sensory apparatus. Examples of such 'inattentional blindness' include a study by Simons and Chabris (1999), who asked human volunteers to monitor particular aspects of a crowd scene; the volunteers were so intent on the task that most failed to notice the irrelevant but surprising presence of a man in a gorilla suit in prominent positions within the crowd.

Perceptual deficits in brain-damaged individuals have also contributed to our understanding of this level of perception. A classic example is work by Weiskrantz and colleagues on 'blindsight' in humans and non-human primates with damaged visual cortices. These individuals are unable to see stimuli on the affected side, even though their eyes are undamaged. However, if asked to guess characteristics of the stimuli, they are correct more often than chance would predict, suggesting that they can subconsciously see the stimuli but that they do not experience any visual **qualia** on that side. Therefore, there appears to be a distinction between conscious and sub-conscious perception, at least in the primate species studied thus far.

From an applied animal behaviour and welfare perspective, an individual's sensory biases will be important, as well as the way the individual evaluates stimuli, i.e. the emotions or motivations that relevant stimuli provoke.

Sensory perception

The type of stimuli that can be detected and perceived will depend on the animal's sensory apparatus, and this can differ markedly between species and even between conspecifics. Therefore, each individual might detect different aspects of the world, giving it a distinct perception of stimuli from other individuals. Moreover, natural selection means that the type and range of senses that a species possesses are tuned to ethologically relevant stimuli. For example, **nocturnal** animals either have extremely sensitive vision or rely much less on that sense than their diurnal relatives would; they communicate not with visual displays, but with sound or scent, and their hearing and olfactory apparatus will be highly tuned towards detecting signals from conspecifics and predators or prey.

In humans, we traditionally divide the senses into five modalities: vision, audition, **olfaction**, gustation and somatosensation. Sometimes differences between humans' and other animals' sensory abilities take the form of shifted

sensitivity ranges within a sensory dimension, e.g. elephants hear lower frequencies of sound than humans (infrasound), while many small animals hear higher frequencies (ultrasound). Similarly, while many non-human primates have similar trichromatic colour vision to humans, most other mammals have dichromatic vision, which extends into the ultraviolet in some species. As for birds, most have tetrachromatic vision, allowing extremely fine colour discrimination and often extending into the ultraviolet. Bees and octopuses can see polarized light, and pit vipers and some boas have infrared detectors in their snouts for 'seeing' warm-blooded prey. Most vertebrates are much more reliant on olfaction than are humans, using scents to discriminate between food items, predators and familiar and unfamiliar places, and to communicate with conspecifics.

The vast majority of these communications are ones that we cannot currently understand or monitor directly, and we may even be unaware that they occur. However, we have harnessed dogs' superior olfactory abilities for various applications, including training them as 'sniffer dogs' for detecting illegal substances, finding individual humans or identifying certain cancers. We can also influence animals' behaviour through chemical sensory means, either deliberately (e.g. using anxiolytic pheromones to help reduce behavioural problems in cats and dogs) or inadvertently (e.g. stressing laboratory rodents can cause them to release an alarm odour that increases stress in nearby conspecifics in an uncontrolled manner).

Some animals use senses that have no real equivalent in humans. Examples include **echolocation** in cetaceans, bats, swiftlets and oilbirds, which locate objects by emitting sounds and monitoring the delays in echoes deflected by the objects. Platypus, some fish, sharks and rays can detect weak **electric fields**, including those generated by the movements of other animals, predators or prey; this sense is known as **electroreception**. A final example is **magnetoception**, by which some birds, reptiles and crustaceans can detect spatial changes in the earth's magnetic field; indeed, despite thousands of years of domestication, chickens have retained their magnetoceptive abilities (Freire *et al.*, 2005). This sense is also one that, along with vision and olfaction, allows homing pigeons to navigate long distances, an ability that has long been recognized by humans using pigeons for delivering messages and in competitive racing.

For any animal behaviour experiment, it is important to be aware of the sensory abilities and limitations of the study

P.461

species and even the individuals themselves (e.g. in case of impaired vision or audition), to ensure that they can perceive the relevant stimuli. Animals are slower to learn tasks when non-salient cues are used, e.g. rats learn significantly faster with olfactory or tactile cues compared with classic operant tasks that use coloured lights. Understanding an animal's sensory biases can also help ensure that the experiment is not confounded by cues we cannot perceive. The well-developed olfactory abilities and **communication** of rats and mice have hampered many experiments in this way. For example, rats observing a conspecific demonstrator complete a task to obtain a reward appeared to be able to imitate the demonstrator's actions, but Mitchell and colleagues (1999) later discovered that the rats were actually responding to attractive scents that the demonstrator left in key locations on the apparatus.

Where the sensory capabilities of captive animals differ from those of humans, welfare problems can be caused by stimuli that we cannot easily detect, making the problem particularly difficult for us to understand and to solve. For example, rats have very sensitive vision for low light conditions, which means that captive individuals can suffer retinal damage from lighting that is comfortable for humans. They also have ultrasonic hearing and communicate using ultrasonic **vocalizations**, and some apparently silent laboratory equipment, such as computer monitors, produces loud ultrasonic sounds that might harm their welfare. The ultraviolet vision of birds can also mean that their behaviour is affected, and their welfare possibly decreased, by the ultraviolet-deficient lighting in captivity, as shown by Cuthill and colleagues' research.

Evaluative perception

From an applied animal behaviour perspective, the way animals evaluate stimuli to potentially generate an appropriate behavioural response is one of the most important aspects of perception. Many of these evaluative processes can be unconscious but others may involve some form of awareness (attention, sentience or consciousness). In sentient animals, perception may generate certain emotions and motivations in relation to a stimulus, e.g. a perceived predator might generate fear, while a familiar playmate might generate pleasure or excitement. Equally, the same stimuli might be evaluated very differently by different individuals. For example, the same male mouse scent might be perceived as threatening by a subordinate male conspecific, attractive by a female conspecific, unhygienic by a human and appetizing by a cat.

The way stimuli are evaluated can be determined genetically (i.e. through natural selection), especially when the stimuli have important ethological significance. For example, rabbits, rats and mice, even those bred for generations within laboratories, respond fearfully to predator odours. This rapid, innate evaluation of the odour as dangerous would enable the

animals to behave appropriately even on their first encounter with a predator. Genetically constrained responses are also found in reproductive contexts and in very young animals, where perception of crucially relevant cues and rapid appropriate responses to them are very strongly selected for; examples might include sign stimuli, like the red spot on a herring gull's beak that induces its chicks to peck it for food.

Within an individual's lifespan, experience and learning can also affect the way stimuli are evaluated. Association of a conditional stimulus with an unconditional one usually describes a situation when an animal learns to perceive a detectable but previously irrelevant cue as relevant, because it predicts a relevant event. If the conditional cue predicts a food reward, an animal might learn to perceive it as having a positive meaning, and may even start to show feeding **appetitive behaviour** in response to it. **Ivan Pavlov's** dogs are an example, with the sound of a bell attaining relevance as a predictor of food, even inducing salivation. At the other extreme, some animals learn to fear humans wearing particular clothing, because of associations between the uniforms and past **aversive** events.

Many behaviour problems in **companion animals** can be because of the way that the animals evaluate stimuli, e.g. dogs perceiving other domestic animals as prey or perceiving human visitors as a threat. Therefore, some corrective training techniques aim to change the way in which the animals evaluate relevant stimuli. To illustrate, a horse might shy at the sound of a squeaky gate, evaluating it as some kind of threat, but careful systematic desensitization (**see: Desensitization - systematic**) might eventually mean that the horse would start to perceive the sound as irrelevant, requiring no behavioural response.

The animal's current physiological and psychological state can also affect the way it evaluates sensory information. The hormonal state of an individual can determine its attraction or aversion to relevant stimuli, such as female mammals in **oestrus** becoming more attracted to males, or birds that usually have no apparent interest in sticks collecting them in springtime to build nests. On a different physiological scale, when animals are deficient in certain nutrients, their appetite for those specific nutrients becomes exaggerated and they perceive foods containing them as being particularly attractive ('state-specific appetite'). Then, once they have consumed enough, or too much, of those nutrients, those foods become unattractive or even aversive ('state-specific satiety').

Examples of animals' psychological states influencing their evaluative perception include findings from **cognitive bias** studies in humans and other animals, showing that when individuals have recently experienced negative events, in extreme cases becoming depressed, they evaluate ambiguous cues as being more negative (Mendl and Paul, 2004). In this way negative experiences can lead to animals behaving in ways that reduce the risk of experiencing further negative events. Similarly, when animals are trained to expect a large reward and are instead given a moderate reward (a situation known as successive negative contrast), they show a much less positive response towards that reward than animals which were originally only trained with the moderate reward.

In summary, perception is a hierarchical process that generates a subjective representation of an individual's situation in the world, involving varying levels of sentience and consciousness. It is relevant to applied animal behaviour science in terms of the kinds of sensory stimuli that individuals can detect and the ways in which they evaluate them. Understanding an individual's perceptual biases can help us to refine experimental designs, to solve behavioural problems and to improve the individual's welfare.

Perching behaviour

Many birds will settle either standing or sitting on branches of trees to rest, a behaviour referred to as perching. However, not all birds are able to perch, as this behaviour requires suitable foot anatomy. Perching birds usually have three toes facing forward and one toe pointing back, which enable the bird to grip around the perch. Passeriforme birds, which make up over 50% of all bird species, are all able to perch but many species of Galliforme birds are also able to perch.

Perching is a highly motivated behaviour that is considered to be one of the most important behaviours to laying hens, and it has been shown that hens will work for access to a perch. Under commercial conditions, if there is limited perching space, hens will compete with each other to obtain a place to perch, particularly at night. Perches enable birds to move around at different levels and perch for rest. While perching, birds will also often perform other behaviours such as **preening**.

Perching behaviour is particularly common at night, when many birds will perch sitting in branches of trees throughout the dark period (**see: Roosting**). Birds seek out places to roost well before dark, even on short winter days, and it has been shown that the cue to go to roost is a reduction in the light intensity below a certain level. As dark approaches, birds become very active as they search for a suitable roosting site. Many species of bird, including species of parrot and groups of free-living hens, have preferred roosting sites within their **home range**, and flock members will move to these sites at night. Birds that perch in elevated locations with other flock members at night reduce the risk from ground predators and also benefit through heat conservation.

Even when there is enough space, hens have been observed to perch tightly together, suggesting they prefer to roost together. Under commercial conditions, hens will spend as much as 85% of the dark period roosting on perches, if provided, and if a perch is unavailable at night or access to their usual perch is prevented, hens will walk around more, attempt to perch at alternative sites and take longer to settle. During daylight hours, the amount of time spent perching may depend on a number of factors, including availability of perches, opportunity to perform other behaviours and breed. Hens in wire-floored cages that provide perches will spend between 25 and 50% of the light period perching, although there is much individual variation. This is less in pens with a litter floor.

Hens tend to prefer high perches and, when roosting at night, hens will all choose the highest available perch. Selecting higher perches may also be associated with dominance in some birds, and this may commonly result in problems with owners of parrots who allow their birds access to high perches. Experimental evidence has shown that hens do not show any preference for different perch shapes and designs. However, different perch design can result in differing foot damage. Evidence suggests that, in general, perches with a rectangular cross-section cause less damage than those with a circular cross section. Rectangular perches result in less keel bone damage than circular ones, but round ones with flat upper and lower surfaces appear to result in even less keel bone damage and fewer bumblefoot lesions and allow good grip. For budgerigars, irregular perches are recommended for this reason, and it is recommended that various irregularly sized perches are used in order to exercise the feet and prevent foot problems.

The development of perching behaviour is affected by early experience. Chicks must learn to roost when young. Under natural conditions, junglefowl and feral hens will roost on the ground while their chicks are young and, when they are about 6 weeks of age, the hen will begin to take chicks on to lower branches at night for roosting, encouraging them to fly up with a 'roosting call'. Chicks reared under commercial conditions without access to perches are less adept at using them later in life. Learning to use perches at an early age increases the muscle mass and **bone strength** of the birds and enables them to use the perches better as adults. It also helps birds to develop the cognitive skills necessary for moving around in three-dimensional space. Rearing chicks without access to perches before 4 weeks of age can result in a number of additional problems, such as an increase in the incidence of cloacal cannibalism and aggression, as well as an increase in eggs laid on the floor rather than in the nestboxes. In addition, rearing without access to perches seems to impair the spatial skills of the domestic hen, and its effect may be both pronounced and long lasting.

As well as providing the opportunity to perform an important highly motivated behaviour, making perches available to birds may reduce welfare problems through improved muscle and bone strength. As birds step on to and off a perch, they exercise their muscles and increase dynamic forces on the tibia, resulting in increased muscle and bone mass and strength. When a bird sits on a perch, it has to constantly contract its muscles to grip and support its weight. Despite improved bone

P.463

strength, the provision of perches within commercial laying **hen housing** can result in an increase in injuries, particularly to the keel bone in hens. It is likely that this is due to collisions when jumping on to or between perches. Studies have demonstrated that jumping downwards between perches at steep angles causes difficulties for hens, and these difficulties increase with greater inter-perch distances, which may increase the risk of **injury**.

In conventional battery cages, birds are unable to perform this important behaviour - one of the reasons conventional cages are being banned within the EU. However, in enriched or furnished cages suitable perches must be provided for the hens. Another of the most common currently used alternative systems of **egg production** is the perchery system. The use of perchery or aviary systems for laying hens, and the provision of perches for other species of captively housed birds, may improve welfare through providing a more complex environment and improving bone strength, but care must be taken in the design and positioning of perches in order to prevent injuries.

(RJNM)

Performance testing

Performance testing involves recording the **phenotype** of animals for one or more traits, with a view to identifying those animals most likely: (i) to be useful within a generation; and/or (ii) to produce the best offspring. The traits can be anything that can be objectively measured or subjectively assessed. In **companion animals**, particularly dogs, various aspects of behaviour are typical traits that are performance tested. This applies most commonly to organized breeding programmes for guide dogs and sniffer dogs. Performance testing is also widely used in breeding schemes for the control of multifactorial disorders, such as hip and elbow dysplasia. It is also used in a wide range of farm animals to select for increased productivity, e.g. milk yield, and reduced **disease**, e.g. **lameness** in dairy cattle. It is also used in some countries in the selection and grading of stallions. There is the potential for performance testing to be used for the comparison of different first-crosses among dog breeds for suitability to a range of environments in which dogs are kept, ranging from flats to backyards to 2 ha blocks.

In typical cases, the traits being performance tested are multifactorial, meaning that their variation results from the combined effect of a range of genes and non-genetic factors. For such traits, the procedures of quantitative genetics developed and utilized successfully in production animals can be applied equally to other species. First, estimates of genetic and phenotypic variances and covariances must be obtained for the relevant set of traits; then selection indexes can be calculated, providing the best possible predictions of: (i) future performance within that generation; and (ii)

performance of progeny in the next generation. In the case of multifactorial disorders, this latter prediction is couched in terms of the expected incidence of affected offspring from each potential parent or the expected score for the disorder in the offspring of a potential parent. Both types of prediction are based on a multi-point scoring scheme reflecting subjective assessment of a phenotype, such as a radiograph in the case of hip or elbow dysplasia.

(JA, FWN)

Peripheral nervous system (PNS)

The PNS is that part of the nervous system that extends beyond the **brain** and spinal cord of vertebrates and is typically not specifically protected by hard structures. The peripheral nervous system is divided into different systems in a variety of ways, which can lead to some confusion. The afferent nervous system (or sensory nervous system) consists of those **neurons** within the PNS that carry signals from sensory receptors towards the **central nervous system** (CNS), while the efferent nervous system (or motor nervous system) is the part that conveys signals away from the CNS to effector structures like muscle and endocrine glands.

However, the PNS may also be divided on the basis of the types of structures served; thus the somatic nervous system may be considered to consist of the part involved in the maintenance of posture and movement (i.e. the supply to and from those structures that primarily effect skeletal muscle tone). The visceral nervous system may then be considered that part which serves other structures, such as the gut, skin, etc. However, this distinction is not necessarily reliable, with some including part or all of the nerve supply from the exteroceptors (sense organs detecting external stimuli such as the eye, nose, tongue and skin) within the somatic nervous system. For some, the visceral nervous system is synonymous with the **autonomic nervous system**, while for others the latter is one component of the former, being limited to the peripheral innervations of those structures associated with the **stress** response. In this case, the nervous supply associated with the neurological coordination of visceral organs involved in the process of digestion may be considered to belong to a separate enteric nervous system.

The autonomic component of the peripheral nervous system may be further divided into the **sympathetic nervous system** (which broadly prepares the body for action) and **parasympathetic nervous system**, which largely antagonizes the effects of the former. Further confusion may arise because both the peripheral and parasympathetic nervous systems may be abbreviated to PNS.

(DSM)

Personality

There is no universally accepted definition of personality, even within the human psychological literature, but the term 'personality' in animals is often used to describe the biologically based behavioural tendencies of an individual and refers to the relatively stable phenotype arising from interaction between the **genotype** and environment that produces consistency in behavioural style, but which also differentiates the individual from other members of the same species. In general, consistent behaviours (habits) that are correlated form traits (although it should be noted that certain behaviours may be related to different traits depending on the context in which they are elicited), and it is the traits that define the personality of the individual. Traits and habits are not synonymous. For example, if an animal runs away from an umbrella when it is opened, it has a habit of avoiding opening umbrellas, but if it tends to avoid a range of other unusual circumstances then we may say it is neophobic, or fearful of new things, which would be a trait. It is also important to distinguish personality from ability. The latter focuses on maximal performance capacity, while the former is more focused on typical performance.

P.464

The term is used synonymously by some authors with '**temperament**' and '**behavioural syndrome**', although some differentiate these terms. The term 'personality' is avoided by some, in order to avoid accusations of anthropomorphic bias (**see: Anthropomorphism**). In the human literature, 'temperament' is often used to describe inherited, relatively stable behavioural tendencies that are apparent early in life and form the basis of personality. However, in the animal literature the term temperament may be used to focus attention on relatively stable, emotionally dependent behavioural dispositions. Thus, from this perspective, fearfulness may be considered an aspect of temperament, but independent problem-solving ability would not, although it might be considered an aspect of personality.

The term 'behavioural syndrome' is frequently used within the context of **behavioural ecology** to describe collections of correlated behaviours expressed within a given context or across different contexts. The focus in this context is often the

adaptive value of such predispositions, with different biases assumed to be superior in different contexts. This ecological approach also logically leads to the inference that certain expressions may be **maladaptive** in certain contexts and give rise to problems in certain environments, or that disorder in the underlying mechanism of a trait is possible giving rise to pathology or dysfunction. These concepts have not been given much attention in the animal literature, but deserve careful consideration. While it is possible to study single/narrow traits in isolation (e.g. by developing a specific scale), this approach does not necessarily relate traits to a more general framework of personality, which can lead to confusion and, potentially, be problematic.

Other major focuses of personality research include: the role of environmental and genetic influences on the development of personality, its physiological and neurological basis and the relationship between cognitive styles and personality (i.e. how personality affects the way things are perceived and evaluated).

Gosling *et al.* (2003) have suggested there are three necessary criteria for the establishment of personality in animals: (i) ratings should relate to real attributes of the animal; (ii) assessments by different independent observers must demonstrate reliability; and (iii) assessments must have predictive validity. Personality may be inferred from direct measurements of a range of behaviours that may be related in some way (such as behaviour in social situations) or subjective ratings of more holistic traits (e.g. gregariousness) and, in general, the latter are not only easier to undertake, but may also show greater reliability.

Although different personality traits may be identified from different behavioural focuses and there are potentially thousands of ways to describe the personality of an individual, one review across species, including octopuses and a range of vertebrates (Gosling and John, 1999), suggests that three traits appear quite consistently: (i) extraversion (arousal and sensitivity to reward, possibly linked to Gary's behavioural activation system (**see: Emotion**), sometimes described as boldness, curiosity, energy, exploratory tendency, neophilia, novelty seeking, sociability, surgency or vivacity); (ii) neuroticism (sensitivity to novelty or potential punishment, possibly linked to Gray's behavioural inhibition system (**see: Emotion**), sometimes referred to as emotionality, reactivity, fearfulness or nerve stability); and (iii) agreeableness (tendency to bond, sometimes referred to as affection, affability, affiliative tendency, affinity, altruistic tendency, aggressivity, fighting tendency or hostility, trust).

However, the equivalence of these traits cannot be assumed in different species, especially when there is no evidence of contextual and physiological similarity. It also needs to be considered that human perceptions of personality may largely reflect their own biases in perception rather than any consistent differences in the subjects being observed - for example, if a report-based psychometric instrument developed for use in people is applied to a non-human species, it should come as no surprise that the same structure is revealed in the non-human species.

The recognition of the potential importance of personality in animals has significant implications for animal science. Not least, it provides another dimension against which the suitability of experimental subjects in a given context can be assessed (**see: Individual differences**). Gosling also argues that the recognition of animal personality will facilitate a greater understanding of the biological basis of human personality, by facilitating the exploration of biological continuities through the exploitation of relevant animal models. Animal models potentially allow personality to be studied in a more controlled environment, with the manipulation of specific factors of potential interest with fewer confounding variables.

Personality in animals is also of practical importance, as animals with a particular personality may be more or less suited to certain environments and thus be at different risk of welfare and management problems in the captive environment or survival if being reintroduced as part of a **conservation** programme. They may also differ in their suitability to undertake different tasks, e.g. working/competing horses and dogs.

The study of human personality is also of practical importance in animal science - for example, the personality of those responsible for the care of animals (e.g. **stockpersons** and owners) has recently become an area of interest for those studying animal welfare and behaviour problems (e.g. Podberscek and Serpell, 1997; Hemsworth and Coleman, 1998).

P.465

Pest control - ethics of

Animals are considered pests when they are found in locations where they are not desired and where they cause damage to human property. Of the vertebrate pests, rodents probably constitute the largest problem. A considerable proportion of the world's food supply is lost to rodents, and rodents also spread some serious **diseases**; thus there is an obvious need for rodent pest control.

Whereas the **euthanasia** of laboratory **rats and mice** may only be carried out by trained personnel following detailed guidelines, a wide range of methods for killing these animals when considered pests are available to the general public. The most widely applied method is through bait poisons with anticoagulants, which when ingested cause death from internal bleeding after a prolonged period of disease, presumably accompanied by considerable **distress**. Many other commonly used methods also raise serious **welfare** concerns (Mason and Littin, 2003). The negative image of 'vermin' and the fact that the presumably distressful deaths occur out of human sight probably contribute to this discrepancy in which methods are accepted to kill animals of the same species. Given the detrimental consequences if rodent populations are not controlled, it can be argued that there is a much stronger human interest in such pest control than in most other cases when animals are killed.

Irrespective of the view on how to balance human and animal interests, there seems to be consensus that animals should not be made to suffer unnecessarily. There are methods for rodent control that cause little or no welfare problems, and Mason and Littin (2003) suggest rodent-proofing buildings, the use of well-designed and monitored snap traps or electrocution traps, cyanide gas and alphachloralose bait poison. However, these methods may be less convenient or more costly than currently predominant methods.

The view as to which animals are pests is not constant. For example, large carnivores, such as wolf and lynx, have been heavily hunted and continue to be disliked by the owners of potentially preyed domestic animals, but are now protected in some countries where wild populations still remain.

Pest species - welfare of

Innumerable unwanted, free-living animals are routinely trapped, snared, poisoned, shot, gassed and otherwise killed or managed as part of strategies relating to environmental protection, **conservation** (including **wildlife management** and the control of **urban wildlife**) and the protection of human and animal health, safety and comfort. Pest control carries inherent risks to animal welfare. The risks are to 'target' animals that are killed by the control agent, target animals that are subject to control but are not killed (e.g. those that consume a sublethal dose of poison or that escape from a trap), non-target animals exposed directly to the control agent (e.g. primary poisoning, by-catch in traps), and - when pesticides are used - non-target animals exposed to poisoned carcasses. Target and non-target animals that are not exposed to the control agent can also be indirectly affected positively and negatively by impacts on their environment and on animals with which they interact or on which they depend.

Historically, there has been little concern for the welfare of animals deemed to be pests, but growing attention from the public and animal welfare non-governmental organizations is driving more research and regulatory change to benefit pest **welfare**.

Vertebrate pest animals are no less capable of experiencing **pain** and **distress** than other vertebrate animals. Indeed, they may experience more than other animals in some cases, owing to the actions inflicted upon them and to the types and degrees of **suffering** of which they are capable.

There are several explanations as to why this pain and distress might have been ignored:

- It normally happens unseen and we can therefore ignore it, remain ignorant of it or convince ourselves that we are not to blame for it.
- Pests are not valued as highly, and their suffering is considered easily justified on the basis of the needs of the **health** and **well-being** of humans, domestic animals and the environment being more important than those of pests (i.e. the harm that pests do is considered to outweigh the harm done to them) (**see also: Ethics**).
- Wild animals are subject to similar levels of suffering and a less than ideal manner of death in their daily lives, so what we do is considered less of a concern.
- Some common definitions of animal welfare do not fit with pest control, where the aim is to curtail normal freedoms, happiness and so on or to cause ill health or **death**. The lack of a concept to grasp, or definition with which to work, can be used as a reason to delay progress.
- Cases of domestic **animal cruelty** or animal mistreatment, where the human cause is clearer or mitigation easier to effect, are more easily tackled.

Why should we be concerned about the welfare of vertebrate pest animals? First, they can experience pain and distress and it has been argued that all animal suffering should be minimized. Secondly, it has also been argued that people are responsible for solving problems that they create: in many cases, it is introduced wildlife that causes particular problems. If we introduced the wildlife, we must control it and we must limit the amount of suffering we cause when we do so. Thirdly, there may be a legislative requirement to do so (for instance, to assess the animal welfare impacts of a pesticide when applying to register it for use in some countries). Fourthly, growing public awareness and concern means that the use of some more inhumane pest control methods is becoming less and less acceptable in some countries (for instance, the use of snares, leg-hold traps, strychnine, drowning, burrow fumigation with toxic 'tear' gas and glueboard traps is increasingly being debated).

A wide range of vertebrate animals are controlled, from mammals, birds and fish to **reptiles** and **amphibians**. Accordingly, control methods are wide ranging. Lethal methods include: shooting, **hunting** with bows (e.g. big game), hunting with dogs (e.g. **pigs**, game birds) and other animals (e.g. rabbits), explosives (e.g. for **roosting** animals), electrocution (e.g. **rodents**, roosting animals), traps, nets and snares, poison

baits, injections, fumigants and gases, encouraging **disease**, the introduction of predators, fishing, burrow collapse, drowning (including drowning of trapped aquatic and terrestrial mammals) and methods of preventing lactation so that milkdependent young die. Non-lethal methods include: live capture traps from which animals are later released, repellents and deterrents, physical barriers such as exclusion fences, and control of fertility or **breeding**.

All pest control methods have some impact on animal welfare. An ideal control method would be one that is completely effective but does not cause any suffering. There is currently no such ideal method. Hence, it has been suggested that we should use only the most humane control method available (i.e. one that causes the least amount of pain and distress), improve the humaneness of existing methods and conduct research to find more humane tools.

Reducing the pain and distress caused by existing tools can be as easy as following best practice when using it (e.g. ensuring that a lethal dose of poisonous bait is consumed, or using appropriate firearms and ammunition when shooting). It is easier with physical methods than with poisons, due to the extensive research required, for instance, on drug-poison interactions, appropriate doses, methods and routes of delivery, impacts on the safety of human users (including the possibility of intentional misuse) and domestic animals. There is thus a growing drive to find alternatives to existing methods.

Common definitions of animal welfare do not fit with pest control, where the focus is not on 'happiness', health or natural behaviour but the aim is to curtail normal freedoms or to cause ill health or death. Instead, a notion of welfare as the absence of suffering (in terms of pain, distress and so on), caused by compromise in each of five domains relating broadly to the **five freedoms**, seems the most applicable (see Sharp and Saunders, 2008). Considering the total animal welfare impact of pest control means thinking about all of the effects of the pest control in each of these domains, both intended and unintended, and on all sentient animals impacted. *All animals* includes target and non-target animals, such as dependent young or members or those of the same or another species or group.

There are published guidelines for assessing the impacts of pest control tools on animal welfare. There are also several reviews of animal welfare impacts of vertebrate pest control tools that outline methods for their assessment. Sharp and Saunders (2008) proposed a model for a 'systematic, comprehensive and transparent process that helps to generate consensus among diverse stakeholders regarding the humaneness of control methods'. The model also allows the relative animal welfare impact of different control tools to be compared. The animal welfare impact of most control methods has not been assessed. Some reviews are listed in 'References and further reading' below.

How can pest control be justified, given its impact on animal welfare? From a utilitarian perspective, pest control might be justified if the positive impacts outweighed the negative impacts. However, because pest control affects people, animals and the environment, the interests of all three should be considered when considering positive and negative impacts. This can lead to a conflict because of differing values placed on each of these. For instance, is it justified to kill several introduced predators to protect a few rare native species? Is it justified to kill sentient animals to protect insentient plants? Pest control should also be necessary: the necessity of control itself and the necessity of killing versus non-lethal alternatives should be considered. Consideration of a list of principles, such as the following, could help to justify pest control and ensure that harm to animal welfare is minimized.

- The aims or benefits and the harms of each pest control programme must be clear. Control should only be undertaken if the benefits outweigh the harms.
- Control should only be undertaken if the benefits outweigh the harms and if it is likely that the aims or benefits will be achieved.
- The methods that most effectively and feasibly achieve the aims of the control programme must be used.
- The method that causes the least amount of pain and distress while still achieving the aims must be used (this requires an assessment of the humaneness of all existing methods).
- The methods must be applied in the best possible way.
- Whether or not each control programme actually achieved its aim must be assessed.
- Once the desired aims or benefits have been achieved, steps must be taken to maintain the beneficial state.
- There should be research to reduce the negative animal welfare impacts of existing control methods and to develop novel methods that cause less pain and distress.

Pet

Any animal kept primarily for companionship. Originally this word was applied to humans, implying inferior size, rank or importance, and was only more recently used to describe

P.467

animals. Because of the inferiority implied, and also because of possible confusion with its use to describe people rather than animals, the term **companion animal** is more usually used in the scientific literature.

(JWSB)

Petting

Petting is an interaction or display of affection and touching or stroking by a human. Many people enjoy a 'bond' or relationship with animals, especially with animals such as cats and dogs, and will frequently stroke or pet their animal. Small mammals, such as mice, **rabbits** and **guinea pigs**, are also touched or stroked regularly as are some domesticated bird species such as budgerigars. Larger animals, such as **horses**, and even cold-blooded animals (poikilotherms) such as **reptiles**, are also frequently petted (see: Companion animal).

Petting behaviour may have been one of the reasons dogs came to live alongside humans. The human tendency to nurture and a need for warmth and protection may have been a primary incentive to domesticate wolves some 12,000-80,000 YBP. Animals that have evolved to live within groups may enjoy being petted more than do members of species that are solitary. Most dogs, for instance, enjoy being petted, reflecting the social nature of the dog pack, where dogs may exhibit **allogrooming** or rest in proximity to one another. Cats, too, although solitary hunters, interact within their **social groups**, and human petting may replace the mutual **grooming** commonly observed among felines.

Petting may have significant health benefits for humans. Stroking an animal may have a calmativ effect. Human **blood pressure** and **heart rates** decrease when a dog is petted, suggesting that a positive relationship with a companion animal may result in a reduction in cardiovascular **disease**. In human-dog contact, concentrations of **B-endorphin**, **oxytocin**, **prolactin** and **B-phenylethylamine** increase in both species during positive interspecies interactions such as gentle stroking. For instance, oxytocin, the hormone thought responsible for **bonding**, doubles its plasma concentrations in both humans and dogs after positive interactions.

Petting an animal gives humans an opportunity for close physical contact with another creature, which may be of particular benefit to those people who live alone or those who have less frequent contact with other people (the elderly or teenagers). As people pet an animal, they also talk to them in a language variant known as 'motherese', the same type of language used with babies. Petting an animal may also be used by humans as a secondary reinforcer for good behaviour in some species such as dogs and horses, an alternative to offering food.

Individual animals may differ in their acceptance of being petted and in the areas of their bodies that they prefer to be touched. This may be related to both the physiology and the **behavioural ecology** of the species. The vibrissae (whiskers) around the mouth of animals such as horses and cats, for instance, may be extremely sensitive, as they have a rich afferent nerve supply and are thought to be important in judging distances and detecting vibrations. Few animals appear to enjoy these areas being petted. Cats demonstrate more negative responses when being stroked in the caudal (tail) region, while more positive responses are shown when they are stroked in the temporal region (between the eyes and ears). The perioral region (chin and lips) is intermediate. Horses are sensitive in areas around the withers, mouth, flank and elbow regions and may dislike certain regions being touched - for instance the ears, eyes or groin. Grooming of horses at the withers, however, has a calming effect.

Traditionally, dogs have been petted along their dorsal region (back), but more recent educational programmes encourage chest and chin stroking, as this is thought to be less challenging to an unknown canine. No observable differences were found, however, in heart rate measurements based on the regions of the dog's body touched when kennelled greyhounds and guide dogs were studied, although heart rates decreased when stroking continued for a significant time.

Acceptance of petting may depend on the individual animal's experience when young. Dogs may become fearful, assertive or even aggressive when touched, especially those that were inadequately socialized when young. Some cats also dislike being petted and will resort to biting or attacking. Cats frequently signal the end of social exchange in this way, which can be a problem (petting **aggression**). Education of animal carers to familiarize their companion animal with being petted all over the body is important (**see: Habituation**). Education of children, who are most likely to suffer bites that require hospitalization, and of other people in the correct way of approaching, handling and petting animals may be influential in enhancing human-pet relationships (**see: Bite prevention programmes**).

Further unwelcome outcomes from petting include disease transmission via skin and saliva. Rabies, salmonellosis, toxocariasis, ringworm and sarcoptic mange are some of the diseases that can be spread from animal to human by petting. Routine precautions, such as washing hands after petting animals, may lower the risk of **zoonotic disease** transfer. For the majority of people, nevertheless, the benefits of petting animals are usually considered to outweigh the disadvantages.

Phenotype

Phenotype is any observable trait or characteristic of an individual, such as its morphology, development or behaviour. The expressed phenotype results from an individual's **genotype**, environmental factors and an interaction between these.

(LMD)

P.468

Phenotypic cline

A phenotypic cline is a gradual change in the **phenotype** of a species across a geographical range (sometimes referred to as character gradients). For example, in the common guillemot (*Uria aalge*), a polymorphism characterized by the presence (bridled) or not of a white ring around the eye and a white line running from this ring to the nape changes in frequency from less than 1% in the south of its Atlantic range to over 50% in the north.

(PE)

Pheromonatherapy

Pheromonatherapy refers to the use of **pheromone** or social **odour** signals in a clinical context to manage behaviour problems (often related to some form of **stressor**) in mammals and birds. In this context, the message usually consists of an artificially synthesized mixture of relatively simple chemicals in a particular combination delivered into the immediate environment of the animal to be treated, e.g. by spray or diffuser. These mixtures are inevitably simpler combinations than those emitted by animals in their natural state, but they are used at higher concentrations. Patrick Pageat, a French veterinary behaviour specialist, is largely credited with the initial isolation of the mixtures that underlie the formulation of many of these products, which are now specifically available for the management of a range of behaviour problems in cats, dogs, rabbits, horses and pigs.

Mills, D.S. (2005) Pheromonatherapy: theory and applications. *In Practice* 27, 368-373

Pheromone

The term 'pheromone' was initially used in 1959 by Karlson and Liischer, and was derived from the Greek word *pherein*, meaning 'to carry', and the suffix *mone* was borrowed from hormone or the Greek word *hormon*, meaning 'to stimulate'. They defined the term pheromone as 'substances secreted to the outside of an individual and received by a second individual of the same species in which they release a specific reaction, for example, a definite behaviour or developmental process'. This definition held true in insect research on pheromones, but however it fell short in light of research in the area of mammalian pheromones. The main point of contention to this definition was the term 'specific reaction'. Mammalian behavioural responses are more complex than those of insects and are affected by a large number of influences and stimuli. Although higher animals' responses are biased by the presence of chemosignals, they do not usually respond in a uniform manner with one specific reaction, and so some prefer the term 'social odour' in these species.

Pheromones are most thoroughly studied in insects; however, more recent research has begun to characterize the functional role of pheromones in mammalian species. Pheromones, like hormones, are chemicals or groups of chemicals secreted by an organism which transmit a message that is detected by receptors. Unlike hormones, however, pheromones must travel outside of the body in order to transmit their message to another organism of the same species that have receptors along and near the nasal and oral cavities. The **vomerolnasal organ** (or Jacobson's/Jacobsen's organ), which lies between the nasal and oral cavities, is the mammalian chemosensory organ most responsible for detecting pheromones. Some pheromones are thought to be detected by receptors in the olfactory membrane (**see: Olfaction**).

Releaser versus primer pheromones

Mammalian pheromones can be categorized as either releaser or primer pheromones. Primer pheromones, also called biostimulating pheromones, elicit long-term effects on the animal's developmental processes or their neuroendocrine/endocrine systems. Releaser pheromones, sometimes referred to as signalling pheromones, on the other

hand, are noted by more immediate and shorter-lasting changes in behaviour. A common example of primer pheromones is those found in adult male **urine**. Prepubertal female mice have been shown to increase production of inositol-triphosphate (IP₃) in response to adult male urine. This increase in IP₃ production has been shown to hasten their maturation to puberty. Sexual pheromones that elicit a standing-to-be-mounted behavioural response are a great example of releaser pheromones, eliciting a short-term behavioural response in the receptive female.

Pheromone secretion

Pheromones can be secreted through any bodily secretion, including urine, saliva, sweat, milk and faeces. In addition, many species have specialized scent glands that are specifically used to deposit species-specific scents. Examples of such glands are those found in male **cats** or lemurs, which spray their scent from glands located near the rectum. Chemosignalling through the urine is one of the most widely studied routes effecting social behaviour. Pheromone signals in wolf urine are used to mark territory and warn unrelated wolves to stay away. Similarly, mice and other social animals secrete a cocktail of molecules through their urine which, together, communicate the individual's social and reproductive status. It has also been shown that young mammals in the presence of same-sex sexual pheromones will enter into puberty sooner than those that have no exposure. Many sexual pheromones have also been shown to increase territorial and social aggressiveness in males and maternal aggressiveness in females. Male mice, following removal of the vomeronasal organ, exhibited a significant reduction in aggressive and **sexual behaviours** and showed no sexual preference in mounting **conspecifics**.

Vomeronasal organ and pheromone transport

The vomeronasal organ is located within the nasal septum, and is tube-like in shape and lined with mucus. It is connected to either the nasal and/or oral cavity via the vomeronasal or nasopalatine duct, depending on the species. Running along the length of the lumen of the tube-like vomeronasal organ is a large blood vessel along with the vomeronasal sensory **neuron(e)s**. The lumen is crescent-shaped and microvilliated, the large blood vessel lining the inside of the crescent, while the outer side is lined with sensory neurons. The entire tube is protected within a hard capsule of cartilage. The vomeronasal nerves run from the vomeronasal organ to the accessory olfactory bulb of the **brain**. The protection of the cartilage maintains the sensory neurons of the vomeronasal organ away from the airflow within the nasal cavity. This system assures that stimulation of the chemoreceptor system is limited to the

P.469

mechanism of vascular pumping. In this way the vomeronasal organ can actually take in non-volatile pheromones such as those often secreted in urine and saliva; many of the pheromones secreted from scent glands and from vaginal secretions are also non-volatile. In order for volatile secretions to be efficiently used as chemosignals they must be accompanied by a transporter protein.

Lipocalins are elicited by the body and bind to volatile pheromones so that they can be efficiently transported in body secretions. They are large proteins, approximately 17-30 kDa, produced by the chemosensory epithelia. Lipocalins bind to volatile pheromones via an odourant-binding site. It has been suggested that lipocalins may have alternative functions in pheromonal signalling aside from their transporter role. Some evidence suggests that lipocalins may also act as chemosignals, binding directly to pheromone receptors. Male mice mark territory using urine deposits, containing non-volatile and volatile pheromones. Volatile pheromones secreted in mouse urine bind to the lipocalins - called major urinary proteins, or MUPs. A mouse may produce up to 15 or more different MUPs in its urine in different concentrations. MUPs are some of the most widely studied lipocalins. They have been shown to continue binding to volatile pheromones following secretion, producing a slow release of volatile pheromones well after the urine is dry. The slow release of volatile pheromones attracts attention from competing mice to the mark. However, it has been suggested that the unique mixture of MUPs in the urine acts as an identifier **signal**, providing a virtual fingerprint of the individual that left it. This identifier signal may be the stimulus that elicits a countermarking response from other males.

The vomeronasal regulation of chemosignalling was originally thought to be a small subset of the main olfactory system. Contrarily, the current projected sensory map of the vomeronasal system is considerably different from that of the main olfactory system. In fact, the target centre for the axonal projections of the vomeronasal sensory neurons is the accessory olfactory bulb. The neural organizations of the olfactory and vomeronasal systems are quite different. The most pointed difference between these two is the axonal relationship with the glomerulus and mitral cells. Olfactory sensory neurons expressing a specific receptor project their axons to a single glomerulus located near the outermost region of the main olfactory bulb, while the axonal projections of vomeronasal neurons, expressing the same receptor, target one of 15-30 smaller glomeruli located within the accessory olfactory bulb. Similarly, mitral cells within the main olfactory bulb send out one dendritic process to receive information from the glomerulus, whereas mitral cells of the vomeronasal system send out

several dendritic processes to gain information from multiple glomeruli, suggesting a role of the mitral cell as the processor for all vomeronasal input of a particular receptor.

Pheromone receptors

Recent research has identified approximately 250 pheromone receptors from three structurally distinct families, referred to as V1Rs, V2Rs and V3Rs. All three classes of pheromone receptors are G protein-linked receptors. These classes of receptors are distinct in the G protein α subunit expressed in the neuron. V1Rs are found in neurons expressing Gai2, V2Rs are found in Gao-expressing neurons while V3Rs are exclusive to neurons expressing Gq/11. Olfactory neurons also generally express mostly Gao. The significance of this difference is largely unclear; however, it is apparent that the neurons of the vomeronasal system express in large quantities only one of the two G protein subunits.

A mutant strain of mice deficient in Gai2 displayed only half the number of neurons carrying V2Rs compared with their non-mutant counterparts. Aggressive and sexual behaviours were investigated in these mice, as these behaviours are known to be altered by pheromonal signalling. These mutant mice exhibited a severe reduction in both maternal **aggression** and male territorial aggression. The mice, however, showed no differences in sexual behaviour or partner preference. These results suggest a distinct separation of function between the vomeronasal sensory neuron types. Further studies were conducted to investigate the role of the receptor types in the prepubertal murine female increase of IP₃ response to male urine, a response which hastens their maturation into puberty. Pertussis, a bacterial toxin that blocks the activity of V1Rs and V2Rs, was shown to have no effect on this primer response. Further investigation of the prepubertal vomeronasal membrane *in vitro* determined that, when cultured with male urine and a V3R antagonist, the IP₃ response was prevented, suggesting a role of Gq/11-containing neurons in this response in mice.

Response to pheromone

Pheromones have been shown to elicit a number of behaviour responses in mammals. Regulation of sexual behaviour is the most widely known function of pheromone **communication**. Certain female pheromones involved in sexual attraction are secreted from sebaceous glands located in or near the mons pubis of the female. In response to pheromones of females in heat, males commonly respond with **flehmen**, a behavioural response involving the lifting of the head and curling of the upper lip. Boars secrete a combination of two pheromones in their saliva, which elicits a wide array of behavioural responses from oestrous sows, including attracting them to the boar's location and initiation of the standing response, which is a stance adopted by oestrous sows signalling that they are ready to mate. Boar urine has been shown to elicit a similar response. This behavioural response is used in production in order to identify sows in **oestrus**. Studies have determined that synthetic boar pheromones used *in lieu* of a live boar or urine are just as effective in detecting oestrus in sows.

Similar to the response found in mice, puberty in female swine has also been shown to be accelerated by the presence of a boar. This hastening to sexual maturation can reduce the time to puberty by as much as 30 days. In addition, lactating sows exhibit a shorter postpartum anoestrus period in the presence of boar. Similar priming pheromones from rams and bucks have been shown to increase the age of puberty in **sheep** and **goats**. Rams are often used in production to induce oestrus in a flock or in order to synchronize oestrous cycling among the ewes, and this is often referred to as the 'ram effect'. Cattle research has revealed that as much as a 3.3-month hastening in puberty in heifers can be achieved following exposure to vasectomized bulls. Bull-exposed cows

P.470

also experienced a shorter postpartum period, entering oestrus as rapidly as 60 days following calving, with a mean difference of 5-10 days faster than non-exposed cows.

One of the few well-characterized single-molecule pheromones is the **rabbit** nipple-search pheromone, a chemosignal found in rabbit milk aiding rabbit pups in locating the milk-producing teats. A similar maternal pheromone has been identified in sows that stimulates a feeding response in piglets. Piglets have been shown to refuse to feed if the odourant is washed off the sow. Post-weaned pigs with this maternal pheromone applied to either their feeder or directly to their snout exhibited increased activity over a 48 h period, and increased weight gain and improved feed:gain ratios over a 28-day period when compared with pigs not exposed to this pheromone post-**weaning**.

More recently, simple fatty acid mixtures, based on the cutaneous secretions of a range of species, have become commercially available for the treatment of a range of behavioural problems in **companion animal** species (**see: Pheromonotherapy**).

Pheromonal regulation of behaviour and physiology is an important consideration in animal production settings. Many production animals are maintained in large group sizes and often at high densities. These practices maintain an environment in which high doses of pheromones are constantly being taken up by the animals. The flooring substrate and waste removal practices utilized may also maintain high levels of pheromones in the environment. The consequences of the continuously high degree of chemosignalling stimuli are not yet known. It is well known that aggressiveness can be drastically altered by the presence of certain pheromones. Reduction or removal of certain pheromones from the housing environment might suppress antagonistic behaviours, thereby improving the welfare of the animals. Reproductive, developmental and neuroendocrine responses may also be altered greatly by the high doses of pheromone maintained in production housing.

Animals as a model for understanding human pheromones

Animal models may not present an accurate representation for the study of pheromone signalling in humans. The human vomeronasal organ degenerates well before birth, and continues to exist only in vestigial form. Similarly, the majority of the pheromone receptor genes identified through animal research are found only as non-functional **pseudogenes** in humans. Only a few functional pheromone receptor genes are identified in humans, and their current functions are unclear. One such receptor, the hV1RL1, has been found to be expressed in the nasal mucosa in humans; however, its role as a pheromone receptor is, as yet, uncertain. It has been suggested that, with complex **language** and communication, pheromone signalling lost its adaptive advantage in the species. However, compelling evidence does exist to support a possible role for pheromones in menstrual cycling. Synchronization of female menstrual cycles (the 'Whitten effect') has been well documented in women housed in close proximity for a prolonged period of time. Primer pheromones present a likely explanation for this response, suggesting the possibility of a role for pheromones in human physiology.

Philopatry

Philopatry is the tendency of an individual to return to or stay in a particular home area. Species that breed at or near their birthplace exhibit natal philopatry, while others that return to the same breeding site exhibit breeding philopatry (or site fidelity). Natal philopatry is often sex-biased, with one sex (usually females in birds and males in mammals) more likely to disperse than the other. It is generally thought that sex-biased dispersal is a mechanism to avoid **inbreeding**.

(PE)

Photoperiod

Photoperiod is the duration of light during a standard 24 h day. It is of ultimate (adaptive, evolutionary) significance to animals because it dictates the windows of time during which certain activities are possible (e.g. **sleep** versus activity). It is also of proximate (mechanistic) significance because it provides predictive information about critical matters such as seasonal changes in environmental conditions (weather, food supply). It is practically relevant to those interested in husbandry of both domestic and captive wild animals, because it plays a critical role in coordinating the different elements of animals' lives on a day-to-day basis as well as on longer time scales, such as seasonally. Timing of extremely important

processes such as **reproduction**, migration, hibernation/aestivation and replacement of body covering (e.g. plumage, pelage) is controlled fundamentally by seasonal changes in photoperiod in many kinds of animals.

Activity cycles of almost all animals, as well as many temporal patterns of physiological activity, such as metabolic rate, hormone secretion and digestive system activity, are controlled fundamentally by endogenous **circadian rhythms**. The only known exceptions are species that live in essentially constant conditions, such as the fossorial naked mole rats. These endogenous rhythms persist in the absence of light/dark cycles, but gradually drift away from the natural night/day cycle (i.e. free-run) if deprived of the entraining effects of light/dark cycles. Aberrant activity patterns (e.g. arrhythmicity) can result if animals evolved to occupy environments typified by night/day changes in light encounter certain unnatural conditions. For instance, many types of bird become arrhythmic if held in constant bright light, whereas very dim light permits these endogenous rhythms to persist.

Circadian rhythms are susceptible to modification by environmental inputs, the most obvious being the entraining effects of the onset of the light period, but also the modulating effects of such factors as food supply and moonlight. Circadian rhythms are regulated by endogenous clocks in the **central nervous system**, particularly in the suprachiasmatic nucleus (SCN) of the **brain**, and these clocks receive modulating

P.471

inputs from various sources, most notably the eyes of mammals (via the retino-hypothalamic tract, a separate pathway connecting certain populations of retinal ganglion cells directly to the SCN, and thence via the brain stem to the pineal). Photoreception for regulation of circadian rhythms in nonmammals is more complex and less dependent on the eyes.

Except for exactly on the equator, photoperiod varies in a highly predictable manner on a seasonal basis. Consequently, it provides extremely reliable information to animals regarding impending changes in environmental conditions that are relevant to survival and reproductive success. Many kinds of animals from all vertebrate classes have been shown to display behavioural and physiological responses to seasonal changes in photoperiod, which are also integrated with inputs from other kinds of cues, such as temperature, food supply/nutritional plane and social interactions with **conspecifics**. Temperature has a particularly strong modulatory effect on ectotherms.

Seasonal changes in photoperiod may act either as drivers of behavioural, physiological and morphological changes, or entrain endogenous circannual rhythms, or both. In the temperate zone, where changes in photoperiod are pronounced, photoperiod clearly plays a dominant role in orchestrating the transitions animals make between different life cycle stages. For instance many temperate-zone birds and mammals are long-day breeders, initiating reproductive development as days lengthen in spring in anticipation of improving environmental conditions, and then terminating breeding prior to deterioration of those conditions in autumn. Examples of long-day breeders include most temperate-zone birds and many rodents. In other species, preparation for **breeding** does not commence until well after the start of the decline in day-length after the summer solstice. Many kinds of large wild animals such as deer, and domestic animals such as sheep, fall into this category. A small but significant number of bird species, and many kinds of fish (e.g. autumn- and winter-breeding salmonids) also breed on declining day-length or even on or near the shortest days of the year.

Both birds and mammals are known to become 'photorefractory', in that at certain stages of the annual cycle individuals cease to display a reproductive response to photoperiod. The terminology used with reference to birds and mammals is reversed, however: long-day breeding rodents are said to be photorefractory when their reproductive axis ceases to be inhibited by short days (i.e. they recrudescence the reproductive system and resume breeding despite continued short days), whereas long-day breeding birds are said to be photorefractory when they cease to maintain reproductive competence despite continued long days (i.e. the reproductive system regresses to an inactive state, sometimes before the summer solstice). Despite this difference in terminology, the neuroendocrine processes underlying the reproductive cycles of birds and mammals are fundamentally similar in many respects.

Although some kinds of animals will display fairly normal seasonal changes in reproductive condition, hibernatory or migratory activity and body covering (plumage/pelage) replacement in the absence of any changes in photoperiod (i.e. circannual rhythms), natural coordination of the full suite of elements to animals' annual cycles is facilitated by natural changes in photoperiod. Some species will proceed from one life cycle stage (e.g. breeding) to the next (e.g. plumage moult and preparation for autumn migration) without any change in photoperiod (e.g. many kinds of temperate-zone and Arcticbreeding birds); however, in the absence of further photoperiodic changes (e.g. a period of short days typical of autumn), many of these will then fail indefinitely to proceed to the next stage after that (e.g. redevelopment of the **gonads** and preparation for spring migration). In fact, expression of endogenous circannual rhythms can be very photoperioddependent, even in those species that display them.

Sensitivity to changes in photoperiod can be fairly exquisite. Taxa living within the tropics but far enough from the equator for there to be small seasonal changes in photoperiod are capable of sensing and responding to changes in photoperiod of as little as 15 min. However, this degree of sensitivity to small changes in photoperiod is not unique to tropical taxa; temperate-zone taxa are affected significantly by changes of as little as 30 min, and perhaps less. Response patterns to particular seasonal photo-regimes can be sufficiently specialized as to constrain species' abilities to cope effectively with rapid environmental changes that alter the optimal timing for reproduction. Effects of the photocycles should be considered very carefully when maintaining captive populations of animals, particularly if breeding is desired.

Phylogeny

Why does the family dog often walk in tight circles before lying down? Can conservationists predict which species will be most sensitive to environmental change? The way animals behave today is dependent to a great extent on their evolutionary history (**see also: Evolution**). While processes such as natural selection can lead to changes in behaviour over very short evolutionary timescales, animals also exhibit traits 'held over' or retained from their evolutionary ancestors. Behaviour can therefore be specific to particular species because of recent and unique selective pressures, or common across groups of closely related species through shared ancestry. Such similarities and differences between species are the raw material of phylogeny.

Broadly defined, phylogeny refers to the evolutionary history of species. This can mean the specific evolutionary relationships among species, or how an animal's appearance, physiology or ecology has been shaped by evolution. Species

P.472

relationships are depicted graphically as a phylogenetic tree. Positioned at the tips of the tree are the names of present-day species, and these are connected by branches indicating how related species are to one another. The fundamental relationships between species are typically inferred through comparisons of DNA sequences (e.g. mitochondrial DNA, or mtDNA), but morphological and behavioural traits are also sometimes used. Once a phylogenetic tree has been developed, the current distribution of a given trait across species can be used to reconstruct the evolutionary origin of that trait. This technique is called the **comparative method** (as distinct from 'comparative psychology') and is a powerful - yet often underused - tool in animal behaviour. Knowing the phylogeny of an animal and using the comparative method can provide unique insights into the origin of behaviour. Phylogeny can also help predict how animals might react under different conditions.

Thinking phylogenetically

‘Even in the psychological field, living organisms are phylogenetically derived entities whose specific origin and form can only be interpreted in the light of their phylogenetic history’ (Lorenz, 1974).

Two influential pioneers in **ethology**, **Konrad Lorenz** and **Niko Tinbergen** (see also: **Tinbergen’s four questions**), emphasized the importance of phylogeny in the study of animal behaviour. Despite this, incorporating phylogeny into behavioural research is seldom done. More commonly, function is interpreted exclusively from the context in which behaviour is observed today. Yet, as Lorenz points out above, only by understanding the phylogenetic history of an animal is a clear picture of its behaviour obtained. For example, the apparently functionless circling behaviour of a dog before **lying** down is puzzling when considered only in its presentday context. We should remember, however, that the domestic dog has its origin with the ancestors of the grey wolf. In the wild, wolves walk repeatedly in circles to flatten down areas of grass or snow before bedding down. We can reconstruct this behaviour back to the common ancestor of dogs, wolves and other canids. From this we can conclude that dogs are expressing a behaviour that has been retained from their evolutionary past.

Understanding the phylogeny of behaviour can serve more practical purposes than deciphering pet psychology. Phylogeny can also provide clues about the behaviour of animals in the wild. The successful preservation of rare and endangered species is greatly facilitated by knowing an animal’s behavioural ecology (see also: **Conservation**; **Wildlife management**). Such information takes time and resources to obtain. Data collection is further complicated if species are located in areas geographically inaccessible to biologists, or when population numbers have declined so low that animals are rarely observed in the wild. However, because closely related species often share traits through common ancestry, we can get at least some idea about the ecology of rare species by observing the behaviour of their better-known relatives. Experiments on more common sister species could also help to determine the potential success of an ambitious conservation strategy (e.g. translocation of animals), without having to disturb the already vulnerable species in question.

Using behavioural phylogenies

‘[The naturalist’s] main source of inspiration is comparison. Through comparison he notices both similarities between species and differences between them’ (Tinbergen, 1963).

Faced with budget cuts, lack of personnel and/or time before species decline into **extinction**, conservationists are forced to make difficult decisions about where to allocate scarce resources. In an effort to help prioritize, biologists have started to develop large datasets of life history, **ecology** and behaviour, representing decades’ worth of work on hundreds of species. With these databases, researchers have begun to use phylogenetic comparative methods to identify the sorts of factors that species vulnerable to extinction typically share. Chief among these seems to be the extent to which species have evolved specializations to particular habitats. In the event that these habitats disappear (through climate change or human activities such as logging), species are forced into habitats for which they are poorly adapted. The result is often population decline and, ultimately, extinction if evolution is unable to catch up with rapid changes in the environment.

On the other hand, the comparative method has also revealed that some traits can evolve remarkably quickly. This can pose a different set of problems for conservationists, because recovery efforts must take into account the potential for rapid specialization. For instance, many island populations of the Caribbean rock iguana (genus *Cyclura*) have become critically endangered through human development and the introduction of predators (cats and dogs). Iguanas use elaborate head-bobbing displays to acquire territories that are vital for reproduction (see also: **Territoriality**). Researchers have found that different populations perform different types of head-bobbing patterns (see Fig. P.1).

This means that lizards brought together in captivity from different islands may have difficulty communicating effectively with one another, and this will in turn jeopardize the success of **breeding** programmes. Furthermore, the phylogenetic analysis of displays reveals dramatic changes in head-bobbing patterns over extremely short time periods, as rapidly as six generations (~30 years). Animals raised from consecutive generations in **captivity** and then reintroduced back into the wild could find it difficult to acquire territories (and subsequent mating opportunities) because they possess a display of the ‘wrong’ type.

The imprint of evolutionary history is apparent in all types of behaviour, from the way domestic pets behave in our home to how animals interact with each other in the wild. Placing animal behaviour in a phylogenetic context is essential for a complete understanding of its origin, but also its present-day function. By comparing closely related species, we can obtain a window into the past and a means to piece together the steps leading to the evolution of different forms of behaviour.

While this information has obvious relevance to the interpretation of behaviour generally, it has practical implications for applied science as well (e.g. conservation biology).

The tendency to ingest non-nutritive items is called pica. Pica has been documented to occur most notably in the domestic **dog, cat and pig (see: Stone chewing)**, although it is seen in other species. A variety of different objects have been noted to be ingested, including rocks, rubber, plastic, paper, card, wool, cotton, silk and synthetics.

The behaviour can occur at any age, although the occurrence of the behaviour in juveniles has been suggested to be part of normal investigative behaviour, particularly with puppies. Onset of the behaviour in the adult has been described as an **abnormal** behaviour. In certain cases the behaviour has been classified as a **compulsive disorder** - for example, when objects are persistently selected as seen in wool sucking or chewing in cats.

The cause is not fully understood, and may be related to an underlying clinical condition or an environmental trigger such as early weaning, stress or separation anxiety. The occurrence of pica in the domestic cat is likely also to have a genetic component, as it has been noted to occur proportionally more in the oriental breeds.

Pig

The pig is a domesticated descendent of the Eurasian wild boar (*Sus scrofa*). The wild boar is a member of the even-toed **ungulates** (artiodactyla), which first evolved in the Eocene epoch (56-34 million YBP), and it has essentially retained the mode of life of the Eocene artiodactyls: an unspecialized diet, absence of horns and antlers and the **carnivore**-like habits of using dens, making nests and bearing litters. Originating in South-east Asia, the wild boar is the most widely distributed member of the nine species of the *Suidae* family. It is found in subarctic, temperate and tropical regions of the Old World, including most areas of Europe, the Mediterranean basin and North Africa, the Russian taiga, India, South-east Asia, Sri Lanka and Japan.

A recent morphological analysis has proposed that four subspecies exist. On the basis of archaeological records, the domestic pig appears to have been independently domesticated on at least two occasions - first in the Near East at around 9000 YBP, and secondly, in the Far East (China) around 4900-7000 YBP. However, recent mitochondrial DNA evidence suggests that up to six separate domestication events occurred, and that modern European breeds are derived from local wild boar populations in central Europe.

Historically, pigs have been kept on a small scale. In early **domestication**, pigs were allowed to roam relatively freely in woodlands surrounding human settlements. These pigs differed little from wild boar except that they were smaller in size, and were more amenable to human contact. As woodland gave way to agricultural land during the Middle Ages, pigs' capacity to damage crops meant that they were increasingly confined, and access to woodland was restricted. In rural areas the world over, and even within urban settings, individual families would rear a few pigs to supplement their diet, in effect 'recycling' waste

P.474

food by feeding it to the pig. During the course of the dramatic changes in agriculture over the last 200 years, deliberate artificial **selection** began to be carried out and pigs grew more rapidly, became fatter and had a larger mature size. Asian pigs, introduced to Europe in the 18th and early 19th centuries, were crossed with local breeds, and the genome of the modern European Large White and Landrace breeds reflect this hybridization. There remain some behavioural and phenotypic variations between breeds, reflecting the differences in selection pressure placed on individual traits, but modern domestic pigs are now much larger than wild boar - mature individuals weighing in excess of 300 kg compared with 35-230 kg for wild boar (see Fig. P.2).

Current farming systems

Pig farming itself in the industrialized world is now one of the most intensive of all livestock production systems. It has moved away from small-scale production, and the ever-increasing scales of commercial livestock operations, influenced by

advances in mechanization, economic pressure and tightening legislation regarding **feeding, transport, slaughter** and meat hygiene have changed the way our animals are kept (**see: Intensification of animal production**). On commercial pig units, animals may now be kept in large buildings, with a high degree of automation to supply feed, water, heat and ventilation and to remove waste. Intensification has been a commercial success because it has reduced costs of production, by reducing feed and labour costs and improving **disease** control. While the trend for fewer, larger commercial units is spreading globally, consumers are now questioning intensification and its effect on the **welfare** of pigs. All aspects of pig production are attracting welfare concerns - **breeding herd housing**, slaughter herd housing, transport and slaughter - with major concerns associated with close confinement and housing in barren, frustrating environments, although outdoor systems also have potential welfare problems, even though they offer a more naturalistic environment (see Fig. P.3).

There are essentially three different types of commercial pig unit: (i) a breeding-only unit, which houses only the breeding herd and piglets commonly up to about 25 kg; (ii) a rearing-/finishing-only unit, which houses the pigs from 25 kg up to age of slaughter; and (iii) the combined unit, which houses both the breeding herd and the rearing/finishing herd up to slaughter. Early-weaning practices in some countries have resulted in greater separation of the various phases of slaughter pig rearing but, in terms of housing and welfare considerations, pig production is essentially split into three distinct phases: (i) the dry sow, meaning all gestating sows, sows awaiting service and barren sows within the herd; (ii) the farrowing sow/lactating sow and her litter; and (iii) the weaned pig being reared for slaughter.

Fig. P.2. Wild boar sow with her piglets (image courtesy of Fritha Langford).

Fig. P.3. Outdoor sow and piglets rooting and foraging (image courtesy of Marianne Farish).

The dry sow

The breeding cycle of the sow already in the herd begins at **weaning** from the farrowing house. After weaning, the sow is usually moved to a special service area with boar contact, which encourages **oestrus**, optimally - from a production viewpoint - at around 4-5 days after weaning. Service itself can either be natural, using a boar, or by **artificial insemination** (AI) or, commonly, a mixture of both. After serving, the sow will typically remain in the service area for 3-4 weeks, where the **stockperson** will watch for any signs that she is not pregnant - i.e. signs of oestrous behaviour at 21 days after service. Typically, between 10 and 20% of sows do not hold their pregnancy, and those that consistently fail will be culled from the herd and replaced by new breeding females, which are called gilts until after the birth of their first litter. Most units will also cull sows at weaning on the basis of age or number of litters, irrespective of whether or not the sow is still producing and rearing good piglet numbers. The mean culling rate for sows is often as high as 40-50%, the majority due to fertility and age reasons, but also including culling due to other causes such as **lameness** and various ailments. Another 5-10% of sows may die annually, thus resulting in an annual replacement rate of 50-60%.

Once the sow does not obviously come back into oestrus, or after pregnancy is confirmed by ultrasound scanning, she will then be returned to the gestating sow system, where she will spend approximately 12 weeks prior to moving back to the farrowing house about a week before the predicted date of

P.475

birth. There is a great diversity of dry sow housing systems currently in use worldwide, ranging from pasture-based systems to close-confinement stall systems. Although the last few decades have seen sow housing moving increasingly away from extensive to intensive, recent legislation in some countries, notably those within the European Union (EU), will reverse this trend as close confinement systems have already become (in e.g. the UK and Sweden) or will become illegal. There are signs that the movement away from close confinement during gestation may spread further than Europe, with major producers in North America (e.g. Smithfields and Maple Leaf Foods) bringing in their own voluntary change.

Until recently, the major factor behind sow housing systems was that of economics of production. Since World War II there has been a steady reduction in the number of individual pig producers, but increases in the number of pigs being kept. The trend away from extensive systems with small herd numbers towards larger, intensive units was initially fuelled in some countries by government-backed price incentives in the 1940s and accelerated during the 1950s as new, intensive, systembased technology was applied.

Troughs and peaks in production and total sow numbers in response to pig prices are a notorious feature of pig production in many countries, and this has also accelerated the decline of the small producer. It made economic sense to increase herd sizes, stocking densities and turnover and decrease labour costs by mechanization wherever possible. The ultimate developments in terms of dry sow housing were those of stalls and tethers. Keeping sows in permanent confinement gave the farmer a number of advantages over less intensive systems for example: (i) increased stocking density; (ii) increased cost effectiveness, as sows on concrete slats with a mechanised slurry handling system have reduced straw and labour costs; (iii) increased ease of management, as the stockperson is able to monitor individual sows easily and adjust husbandry regime where necessary.

Arguably, the degree of skill required to manage confinement systems is also less than for loose-based systems. However, it has since become apparent that such intensive systems, although perhaps conferring some welfare advantages over loose-housed systems, have a number of serious welfare disadvantages and project a negative image of the industry to the consumer.

The farrowing sow

Sows generally move to the farrowing house around 5-7 days prior to expected farrowing date, which itself is usually based on 115 days after service. Just as with gestating sow housing, there is a great diversity of housing types for the farrowing sow, but worldwide (including those countries with little or no confinement housing of gestating sows) the majority of sows give birth in a confinement system of a **farrowing crate** (see Fig. P.4), although this may be only temporarily in place immediately around farrowing itself.

Prior to intensification, sows most often farrowed in open pens with large amounts of straw. Again, economics forced change. As straw use and pen size decreased and litter size increased, piglet mortality - primarily due to crushing - was found to rise. Introduction of crates into this situation was found to reduce mortality back towards pre-intensification levels. Coupled with this effect on piglet mortality, which is the main reason given by farmers for continued usage, crates were also found to confer management benefits, such as reduced labour costs and ease of piglet handling.

Fig. P.4. Conventional tubular metal farrowing crate, with forward creep area and supplementary piglet heating lamp (image courtesy of JNM-F).

The great amount of research on modification of farrowing crate design has yet to improve liveborn piglet mortality much below 10%, and this fact, together with increasing concerns for the welfare of the sow and a desire for alternative systems that require minimal financial input, has led to a re-examination of the factors necessary for defining the optimum farrowing conditions. As with gestating sow housing, there has been recent development of both old and new farrowing systems. A return to basic individual straw pens with farrowing rails has often given increased mortality from crushing, as the sow is given greater freedom of movement without necessarily having either the maternal behavioural skills or the physical ability to carry out careful posture changing. Other designs include circular or oval crates (see Fig. P.5) or the incorporation of farrowing areas into communal systems (see Fig. P.6) and, as with alternative gestating sow housing, these alternative farrowing sow systems present their own set of potential welfare challenges, not just for the sow, but also for the litter.

Fig. P.5. Oval farrowing crate (image courtesy of J.J. McGlone).

Fig. P.6. Experimental communal pen farrowing system (image courtesy of JNM-F).

The slaughter pig

Once weaned, piglets usually pass through a number of different housing systems during their growth, up to the age they reach slaughter weight. The number of changes in accommodation varies, but intensive units typically move piglets at weaning to specialist nursery accommodation and thereafter move pigs only once more, into finishing accommodation. It is not uncommon, however, for pigs to move through four different systems from weaning, each specific for particular stages of the growing phase. The age at which pigs are slaughtered also varies from country to country and is also dependent on the type of product required, e.g. pork, bacon, ham or processed products. Slaughter weights can therefore be anywhere from 60 kg up to 125 kg, with a slaughter age of between 18 and 26 weeks.

As with sow housing, there is a very large variety of housing types for slaughter pigs, but the majority of pigs, including those bred from outdoor-housed sows, are reared indoors. The goal of the producer is to grow the pig from weaning to slaughter in as short a time possible and using as little feed as possible. This is best achieved indoors, where the thermal environment can be controlled and feed wastage minimized. There is, however, much variety, ranging from fully enclosed, fully slatted systems to open-fronted, kennel-type, deep-straw systems with access to outdoor pens. In general, the slaughter pig has been subject to less welfare research than the sow, but this has been a result of political expediency rather than any particular lack of welfare problems.

Transport and slaughter

At some stage in their lifetime, the vast majority of pigs will be transported, except those that are born and then die or are euthanized on the same farm. The number of times and distances over which they are transported will vary depending on whether they are in the finishing or the breeding herd, and on the nature of the pig industry within the country or region in which they are being reared. For example, it is not uncommon for herds in North America to employ multi-site production, meaning that, at weaning, pigs may be transported to a nursery unit and, later on, transported again to a growing and finishing unit. Over the last few decades, the average distances and journey times that pigs have to be transported to reach the slaughter plant have increased as the number of slaughter plants has reduced. The maximum journey time in particular has been the focus of much recent research, with resulting recommendations and legislation in some markets, such as the EU.

If the process of transportation is too stressful for a pig, the ultimate result can be the death of that pig or the pig becoming non-ambulatory or 'fatigued'. In North America, the current in-transit + post-transit mortality and non-

ambulatory rates are around 0.15 and 0.40%, respectively, representing in total around 11 pigs in every 2000 transported. It is therefore in the interests of the producer (and of course the pig) that the stress of transportation is minimized. The transportation and slaughter process can be thought of in terms of its constituent parts, namely loading, transport, unloading, **lairage** and slaughter. All of these parts have welfare concerns and have been subject to a fair amount of research.

Ultimately, the end point of most transportation events is the slaughter of the pig. Once lairage time is complete, the pig is usually removed from the pen and driven towards the **slaughterhouse** manually. The pigs will enter a forcing pen and, from here, they will enter the **raceway**, which may be double or single file, until they enter the restraint system in single file. The restrainer will minimize body movements and make electrical stunning, in particular, easier to achieve. Stunning may be carried out automatically or manually by passing an electric current across the **brain**, or across brain and heart. Alternative stunning methods are CO₂ or argon gassing, which can be carried out with pigs kept as groups. Regardless of stunning method, the aim is to render the pig insensible, and the pig is then exsanguinated by severing the carotid arteries and jugular veins, leading to death.

Piscivore

A piscivore is a form of carnivorous animal that feeds predominantly or totally on fish. The balance of piscivorous species within a given aquatic environment, like any other type of feeder, may have important implications for the ecology and behavioural patterns of other animals of that area.

Pituitary gland

The pituitary gland is divided into two major sections of distinct embryonic origin: the neurohypophysis of neural origin and the adenohypophysis derived from the ectoderm of the roof of the embryonic mouth. The neurohypophysis (posterior pituitary) is comprised of the median eminence (ME), infundibular stem and the *pars nervosa*. The infundibular stem spans

the distance from the intrahypothalamic ME and the lobes of the hypophysis shallowly embedded within the skull. The adenohypophysis (anterior pituitary) is made up of the *pars distalis*, the *pars tuberalis* and the *pars intermedia*.

Projections of hypothalamic **neuron(e)s** project into the median eminence, where they release hypothalamic hormones, such as **corticotropin-releasing hormone (CRH)**, into the hypothalamo-hypophysial portal vessels, thereby stimulating or inhibiting secretion and synthesis of trophic hormones from the anterior pituitary gland. These trophic hormones include **adrenocorticotrophic hormone (ACTH)**, **follicle-stimulating hormone (FSH)**, **growth hormone (GH)**, **luteinizing hormone (LH)**, **prolactin (PRL)** and thyroidstimulating hormone (TSH). Hormones synthesized from the precursor **pro-opio-melanocortin (POMC)** are also produced in the *pars intermedia* of the anterior pituitary, and these include **β-endorphin** and **met-enkephalin**. The *pars nervosa* of the posterior pituitary secretes the non-peptide hormones **oxytocin (OT)** and arginine vasopressin (AVP, also called **antidiuretic hormone** or ADH), which are stored here after manufacture in the **hypothalamus**. Maintaining water balance is a primary action of the posterior pituitary.

Animal behaviour and **well-being** research focuses mainly on the hormones of the anterior pituitary. ACTH, a major regulator of **glucocorticoid** release in the **adrenal gland**, is often used as a measure of physiological **stress**. Adverse or noxious stimuli increase the concentration of ACTH secreted by the anterior pituitary. The gonadotrophins LH and FSH are used as measures of reproductive competence. PRL has many physiological effects, including its effects on lactation in mammals and brooding in birds. PRL responsiveness is also directly and negatively related to the neuronal concentration of **dopamine**, a neurotransmitter directly related to an animal's stress level and stress-coping ability. Animal production research also focuses on GH, TSH and β-endorphin for the regulation of growth, metabolism, feed conversion and appetite.

Placentophagia

Placentophagia describes the act of eating the placenta, normally by the mother shortly after giving birth in eutherian placental mammals. In marsupials, the placenta is resorbed and so ingestion does occur. Placentophagia occurs in both carnivorous and herbivorous species as a normal behaviour, with the notable exception of the camel and many aquatic species. Placentophagia may result in enhanced opiate sensitivity that has analgesic benefits for the mother postpartum, but may also affect **parental behaviour** and **bonding**, with some males of species showing a high level of **paternal behaviour** also engaging in the activity.

Play

Play is one of those topics that everyone seems to know about but is not quite able to define or explain. Recent attempts to develop rigorous, multifaceted criteria by which to identify play have led to the fascinating conclusion that not only do most species of mammals and many species of birds qualify as exhibiting play, but so do 'lower' vertebrates and even an assortment of invertebrates (Burghardt, 2005). However, despite this, play is a relatively rare phenomenon in the animal kingdom, with the most clear-cut cases being among mammals and some birds. Typically, it is behavioural episodes that seem to be performed for their own sake without fulfilling any obvious biological need that are likely to be labelled as play.

To avoid the risk of labelling any immature act by an infant or, for that matter, a cage stereotypy by an adult as play, care must be taken, for if all puzzling acts are thrown together and labelled as play, then the label becomes meaningless. Again, criteria capable of distinguishing between playful and nonplayful actions are critical. Burghardt proposes five such criteria:

- It is not completely functional in either its form or context.
- It is spontaneous, seemingly performed for its own sake.
- It is modified compared with the functional behaviour that it imitates.

- It is repeated in the same form for extended periods of the life cycle.
- It is such that it primarily occurs when the animal is fed, healthy and free of **stress**.

Even detailed criteria such as these need to be applied with caution. For example, many instances of play in adults can be linked to clear biological benefits at the time at which the play occurs. Thus, criteria need to be viewed as a guide, not as a means to pigeonhole behavioural phenomena. A major reason for this definitional difficulty is that play may have differing levels of complexity and may be co-opted for different functional purposes in different lineages of organisms that engage in play. Among **rodents**, for example, play among immature animals varies markedly across a range of species, with some not playing at all, some having rudimentary forms of play and others being extraordinarily exuberant in the complexity of their playful performances. Only some of these species appear to derive developmental benefits from the performance of play. Similarly, while playful behaviour similar to that seen in juveniles may be present in the adults of some species, not all adults engage in such play with any clear connection to functional outcomes.

When considering non-human animals, play is generally placed into one of three categories: social play, object play or solitary locomotor play. Running, jumping and turning without reference to another subject is an example of locomotor play, manipulating objects qualifies as object play and social play is when two or more animals engage in play together. These categories are limited, of course, because the same actions (e.g. running, leaping and turning) may occur in locomotor play

P.478

and during social play. None the less, they do provide a crude classification that appears to reflect something important about the biology of play. After all, some species may only exhibit one or two of these three types of play, and developmental studies suggest that they may have different times of onset and offset. Indeed, there has been considerable debate as to whether there is one type of playful **motivation** that can be expressed in multiple overt patterns, or multiple motivational systems with their own characteristic type of play. Although the matter is still unresolved, the evidence for a multiple systems view is building at the expense of the single-system view.

Detailed studies of these forms of play in various species reveal that, generally, object play involves the behavioural repertoire typical of food procurement, with the most elaborate examples being seen in carnivores with their prey-killing behavioural tool kit. Predatory play, which involves using actual prey as play objects, may be considered a version of object play. A cat playing with a **mouse** or a ball of yarn applies the predatory repertoire to a non-functional, playful context. Locomotor play most typically involves the runs, leaps and erratic movements of anti-predator behaviour, with the most elaborate forms being seen in species most subject to predation (e.g. **goats, deer, rabbits**, mice). Social play, the most widely studied form of play, can involve the behaviour patterns from a variety of functional behavioural systems, such as **conspecific aggression**, sex and **parental behaviour**. The form of social play most often studied is play fighting, which most commonly involves the behavioural repertoire of conspecific aggression although, for some lineages, this competitive form of play involves **sexual behaviour**, especially the pre-copulatory elements (e.g. murid rodents).

While these categories have some coherence in terms of the functional behavioural repertoire that is used, cases where these categories seem to overlap diminish their descriptive utility - for example, tug-of-war games and chasing incorporate object play and locomotor play with social play. At a finer level of behavioural analysis, such apparent cases of overlap may disappear. For example, it has been commonly thought that in play, animals combine the behavioural repertoire from several functional systems, such as aggression and sex in play fighting. However, detailed, descriptive studies have shown that at a micro-level, the sexual and aggressive elements do not combine but, rather, the sex sequence is not commenced until the attack and defence sequence of aggression is completed, and vice versa (Pellis and Iwaniuk, 2004). Therefore, there may be a greater degree of discreteness in the categories of play than may appear at a more molar level of observation. However, this is an empirical issue still requiring resolution.

Play fighting is the most commonly studied form of play, with more known about its form and consequences, and so forms the basis of this entry. When two animals are engaged in a play fight, they try to gain some advantage over one another, such as striking, biting or nuzzling the partner, usually on some specific body target. The subjects then engage in a sequence of attack, defence and counter-attack, leading to the wresting and jostling for position so apparent in play fighting. These targets can be derived from sexual or aggressive behaviour, or indeed, from predatory behaviour. Note that, in the latter, it is really a form of predatory play, with the partner acting as the surrogate prey. Whatever the origin of the target, the play fighting sequence involves a pattern of usage of attack and defence that is not the same as that seen in functional aggression; indeed, it has a cooperative appearance, in that the interaction leads to frequent role reversals.

Play is most often associated with immature animals, with juveniles providing its most exuberant examples. In addition, play is generally thought to occur in a stress-free environment where the basic necessities of life have been met. When directing the play socially, subjects most typically engage in play with partners of the same age and often of the same sex. These are broad trends and they should not mask the fact that there are important exceptions. For example, some species have high rates of adult play, especially in the form of social play that may often be directed at other adults, including partners of both sexes. Furthermore, in some species, social play by immature animals may be directed preferentially at adults rather than at other immature animals. Thus, the general trends should be viewed as guides to the phenomenon, not as substitutes for detailed knowledge of the species under investigation. Indeed, when trying to understand the functions of play and how play may be used in welfare contexts, the peculiarities of the play present in the species of concern need to be carefully characterized.

For a range of species, including birds and mammals, social play among sub-adults and adults often occurs in contexts of social tension or ambiguity, such as when potential sex partners meet or when there is some turmoil in existing **dominance** relationships. In these contexts, playful modes of interaction appear to be useful in either establishing or reinforcing social bonds, or in testing and manipulating social relationships. For a variety of species, especially those that engage in playful interactions as adults, the organization of social play encounters as juveniles is modified in a manner consistent with such interactions that serve to refine cognitive and emotional skills needed for subtle and complex social interactions as adults.

In **rats**, social play mostly involves play fighting. In play fighting, a partner attempts to contact the nape with its snout, which, if contacted, is gently rubbed. The defending rat responds to such an attack with one of a variety of tactics in order to block access to its nape. Juvenile rats engage in defensive actions most likely to prolong bodily contact with their partners - typically by rolling over on to their backs when attacked. The attacker may then hold the defender down with its forepaws while attempting to make further contact with its partner's nape but, more often than not, will stand on the supine partner's belly with its hindpaws. Standing with all four paws on its wriggling partner leads to the rat losing its stability and, indeed, facilitates the defender's ability to counter-attack, thus enabling it to gain access to the original attacker's nape. This configuration of attack and defence behaviour is not present either before or after the juvenile phase - rather, when juvenile, when play is at its most frequent, young rats adopt modes of interaction that increase their experience of instability during social interactions.

Such instability may be excellent training for the physical and emotional vicissitudes to be expected in the rough and tumble of the social world. Learning what to do in such

P.479

situations makes for an adult with a greater range of options in dealing with the unexpected. There are data from a variety of species that suggest that play in general serves to provide such training for this.

Play in adults and in immature animals thus reflects the presence of complex social exchanges and the development of important social, emotional and cognitive skills. As such, the presence of play in captive animals of species that have play as part of their normal repertoire represents an important indicator of their **well-being**. Indeed, as play is most often associated with a stress-free environment, it has been used to monitor the well-being of both free-living and captive animals. Generally, it has been found that animals that engage in play are healthier, better nourished and more socially adjusted than ones that play infrequently. This relationship implies that play is simply a measure of the absence of stress, but there is increasing evidence for a more complex relationship between the two. First, play experience in the juvenile phase may be important in promoting the development of strategies for **coping** with stress as adults. Secondly, there are laboratory data suggesting that engaging in play can reduce stress. It is well known that social **grooming** and huddling can reduce stress, and social play may tap into the same mechanisms. The added advantage of the playful solution to stress reduction is that it combines the benefits of amicable social contact with that of rigorous exercise.

Therefore, under a number of husbandry conditions, in the research laboratory, in the **zoo** and in the farmyard, the presence of play may well indicate the unfolding of speciestypical development, well-adjusted adults and animals capable of dealing with the day-to-day vicissitudes of life. There are, however, some important caveats to bear in mind given that our knowledge of play is still in its infancy. First, in any given case, direct measures of stress, behavioural or physiological, need to be made to ensure that the play being observed is indeed a marker for the absence of stress or stress reduction. For example, in a study of captive squirrel **monkeys**, it was found that while play led to the reduction of stress in the juveniles, the stress levels in the cohabiting adults actually rose. Thus, it cannot be assumed that, if the average level of play is relatively high, then the stress level is uniformly low. In fact, there is some evidence suggesting that rougher forms of social play can be used as a form of 'punishment'; this may lead to subordinate members of the group being stressed when they are the targets of playful interactions with dominant animals.

Secondly, the presence of play may indicate that the animals are in a state of **distress**. For example, in gibbons, there appears to be an elevation of social play when new troops are formed. A reduction in play may thus indicate that a more stable set of relationships within the troop has been achieved, and so, presumably, a reduction in the level of stress. Thirdly, we know that the frequency of play can vary with environmental context, but we do not know what the minimum, baseline level of play may be for any species. Without such a baseline, it is hard to determine what may represent too little or too much play in any particular species in a given context.

In the absence of a baseline for the frequency of play, information on the context and form of the play fighting occurring may be useful, as would information on which individuals are playing with whom. For example, in observations of a troop of captive **gorillas** (Calgary Zoo, Alberta, Canada), the silverback responded to the play overtures of one of his sons, and would sometimes even initiate play with that son. The other son, of the same age, was typically left out and, if he attempted to join in, the silverback would strike him forcefully, inhibiting for a while any further attempts to join the fray. Thus, while all three appeared to be engaged in social play, the experiences, positive and negative, for each individual would probably have been very different. Again, it seems important to examine the details of the play performed.

Even with these notes of caution, it would still seem prudent to use play as a marker for general well-being, bearing in mind that additional data may be needed in order to help evaluate whether the state of play should be cause for intervention. Given the seeming importance of play for many species of mammals and some species of birds, the potential value of this behaviour for animal husbandry and welfare concerns should not be underestimated.

Polydipsia - stress-induced

Polydipsia describes excessive **drinking** behaviour. Polydipsia may arise as a result of physical **disease**, e.g. renal failure, diabetes, etc. or from psychological factors, often referred to as stress-induced polydipsia. This may arise incidentally in animals under chronic **stress** or be induced deliberately. The most commonly induced form is a schedule-induced behaviour, in which the animal is incidentally or deliberately placed on a fixed-interval reinforcement schedule (**see: Reinforcement types of**) for drinking: i.e. the animals may be rewarded with food for drinking after a set time. This tends to increase the amount of drinking that occurs around the time of the interval associated with reinforcement. This procedure in the rat has been proposed as model of obsessive-**compulsive disorder** in people, but its validity is questionable; however, it may explain some forms of repetitive/stereotypic behaviour in captive animals.

shown that not only may a terminal or **consummatory** act that is reinforced increase, but also that other interim behaviours incidentally associated with this act (adjunctive behaviours) may become more common, even if they are not contiguous with the reinforcement (**see: Contiguity**). A range of other schedule-induced behaviours have also been demonstrated, including **aggression**, air-licking, eating and wheel running. Studies of schedule-induced polydipsia indicate that a range of other factors affect the intensity of the behaviour: for example, it is increased when a preferred flavour is used or the animals are underweight and there is a peak interval reinforcement time effect.

(DSM)

Porcine stress syndrome

Porcine stress syndrome (PSS) is a non-infectious genetic disease that develops in (homozygous) pigs expressing the mutated autosomal recessive ryanodine-receptor (*ryr-1*) gene, also called the halothane gene. The individuals expressing this gene are greatly sensitive to the anaesthetic halothane, hence the name of the gene. Genetically predisposed pigs are highly susceptible to acute **stressors**, such as **handling** and **transport**, that lead to a complex of conditions. Malignant hyperthermia, back muscle necrosis (BMN) and pale soft exudative pork muscle (**PSE meat**), followed by sudden death, can develop. These conditions result from a substitution of the nucleotide cytosine (C) for thymidine (T) on the *ryr-1* gene, which ultimately alters the function of the protein ryanodine. The mutated protein facilitates the opening of the calcium channels and inhibits their closure, leading to greater flow of calcium ions and excessive stimulation of muscle contracture.

The expression of this gene is linked with heavily muscled and lean (low fat deposition) **breeds** (i.e. Pietrain). Genetic selection for meatiness and carcass conformation, both economically beneficial traits, facilitated the spread of the disease, characterized by stress susceptibility and predisposition to developing an inferior meat quality. The mutated *ryr-1* gene is also a matter of animal **welfare**, since PSS includes degeneration of the muscle and **pain**, and can cause public concern that diseased pigs may be used for meat production.

Pathological changes in the muscle occur when the cellular metabolism changes from aerobic to anaerobic, developing biochemical abnormalities. The switch of energy utilization results from a prolonged increase in calcium flux through the calcium channels of the sarcoplasmic reticulum. The deficit in the intracellular removal of calcium causes persistent muscle contraction. This state leads to excessive production of lactic acid (acidosis), primarily in IIB white muscle fibres, and increased body heat with poor production of adenosine triphosphate (ATP). An increase in body temperature is an outcome of an exacerbation of muscle metabolism that leads to acidosis and causes constriction of the peripheral blood system.

Norepinephrine and cortisol concentrations are high. Both smooth and skeletal muscles can be affected.

Homozygous individuals can be visually identified by their shorter body and bulging oval hams, with a thin layer of fat. Back muscle necrosis is a particular manifestation of PSS and can be seen in pigs over 50 kg of body weight. Unilateral BMN is characterized by a curvature of the body towards the affected side. Symptoms occur during or following a stressful situation and are initially visible as rapid tremor of the tail and skeletal muscle occur. Pigs may present lesions of erythema (blotched red and pale skin), twitching of the face, tachypnoea (fast respiration), tachycardia (fast heartbeat) and an increased body temperature (>41.5°C). Death is usually preceded by collapse and muscle rigidity, and occurs within 15-20 min from the start of symptoms. Some of these clinical signs may be induced by anaesthesia with halothane. Environmental temperatures above 22°C predispose the condition.

Generalized oedema, congestion of lungs and frothy exudate from the trachea are among the few pathological changes seen. Hepatic congestion and hydrothorax may be observed. There is a rapid onset of rigor mortis, and dark blood caused by oxygen desaturation may occur. The muscle's pH drops to 6.0 or less within 45 min post-mortem. Muscle with a pale, soft exudative appearance can be seen in 60-70% of PSS-susceptible pigs within 15 min of post-mortem. Back muscle necrosis, which is characterized by pale areas of necrosis in the multifidi and longissimus dorsi muscles, is seen when sliced in sections, as the pale areas contrast with the red intact muscle bundles. Histological observation of degenerating and regenerating, in addition to hypercontracted, muscle fibres may be present. Cardiac muscle may show lesions of acute heart failure, such as degeneration and fragmentation.

The clinical diagnosis is established by the development of clinical signs, such as skin blanching and rigidity after the animal is subjected to a stressful stimulus or to a volatile anaesthetic (i.e. halothane). A differential diagnosis of PSS from other fatal diseases (i.e. anthrax, twisted bowel, bloody gut, gastric torsion, electrocution, vegetative endocarditis) is based on

body conformation, breed and the acute nature of the disease in relationship to a stressor like handling, restraint, transport and high environmental temperature.

Laboratory tests are used to aid in the identification of live PSS-susceptible animals, but the procedures are not rapid enough to diagnose the disease in time to prevent death. Polymerase chain reaction (PCR), a DNA-based assay, is used for the detection of the *ryr-1* gene in the blood or tissue and is the most common screening tool, although it may lack sensitivity and specificity to identify PSS-susceptible animals or carriers. It allows identification of homozygous PSS-resistant and PSS-susceptible animals, as well as heterozygous carriers. This technique can also be used in the meat to identify genetically susceptible animals post-mortem. Other tests include the caffeine contracture test, which involves *in vitro* exposure of isolated biopsied muscle tissue to caffeine and halothane, measurement of enzymes and clinical chemistry of the serum. Blood typing also assists in tracing PSS-susceptible animals, along with the *in vivo* halothane challenge test, with 3-6% halothane in oxygen for 3-5 min, which causes susceptible pigs to become rigid and rectal temperature to rise.

Anaesthesia should be discontinued upon development of these clinical signs to prevent death. Measurement of muscle pH from the carcass at **slaughter**, and pale soft exudative muscle consistency, are also indicative of the condition. Due to its acute nature, PSS episodes are usually not able to be treated in time to prevent death. However, pigs that develop PSS under anaesthesia may be successfully treated if detected early.

Animals sensitive to **stress** must be housed in a cool environment with watering areas available (i.e. dripping

P.481

system) and receive adequate ventilation. It is advisable to starve animals 12 h prior to transport, which should be carried out at temperatures below 22°C. Mixing of unfamiliar susceptible animals should be prevented to reduce exposure to social stress, and medication may be used to minimize stress prior to handling, movement or transport.

Genetic selection against the PSS trait is the best tool in preventing or reducing the prevalence of the disease within the swine population. A policy of testing and eliminating PSS-susceptible and carrier animals has been adopted, especially with the advent of DNA-based assays, and has played a major role in controlling the spread of the condition. Currently, several breeds and lines that no longer express the *ryr-1* gene are commercially available. However, breeding of homozygous, stress-susceptible sire lines with resistant dam lines can yield heterozygous animals that have higher carcass quality and prolificacy. Prevention of PSS episodes can be assisted by proper management practices that minimize exposure of animals to stressful events.

Positive welfare

Historically, the scientific assessment of animal **welfare** focused primarily on the **health** of animals and so was dominated by the physical (and physiological) evidential approach (positivism) of the veterinary profession, with recognition of the importance of behavioural parameters emerging after the publication of **Ruth Harrison's** text *Animal Machines* in 1964, which highlighted the biological frustrations associated with intensive farming. This led to a new generation of animal welfare scientists focused on the goal of how to establish the presence or absence of **suffering** in captive animals, as encapsulated in the **five freedoms**. The perspective that good welfare was associated with the absence of suffering (absence of indicators of negative welfare) probably arose as a result of the historical focus on **disease** and the traditional acceptance that animals can feel **pain**, with little consideration given to the relevance of positive **emotions** in veterinary

health care (although it is an interesting historical note that the **Brambell Report**, which led to the production of the five freedoms, acknowledges the importance of pleasure to animals). The extent of animal **sentience** remained very uncertain and, in order to avoid accusations of poor science and **anthropomorphism** in this emerging field, many scientists avoided the subject of specific positive emotional states such as ‘happiness’.

However, in recent years, with an increase in our understanding of the neurophysiological and potentially functional basis of these emotions, there has been growing scientific interest in their assessment in non-human animals, which has started to inform thinking within the field of animal welfare science. This approach has been referred to as a ‘focus on positive welfare’. This focus does not seek to produce methodologies that will replace previous approaches to the assessment of animal welfare but, rather, as with previous innovations, to complement it. In this respect, it has been highlighted that there is an important distinction to be made between the consideration of positive feelings associated with the presence of certain resources or occurrence of certain events (what an animal likes) and the resources or events that it is motivated to achieve (what an animal wants) (Yeates and Main, 2008). Three main approaches to this subject have emerged: one focused on neurophysiological correlates of positive emotional states, one focused on the evaluation of resources that may be desired by an animal and one focused on the behavioural assessment of the relative difference in cognitive or emotional state between individuals in different circumstances or with different histories (**see: Cognitive bias**). However, it must be recognized that the immediate preferences of animals are not necessarily concordant with their long-term interests. Thus indices of positive welfare are not necessarily associated with a high quality of life in the longer term.

Posture

Posture is the arrangement or position of an animal's body and limbs. The basic, normal postures for quadrupeds can be termed ‘standing’, ‘sitting’, ‘kneeling’, ‘lying laterally’ and ‘lying sternally’. Standing and lying postures are often held for relatively long periods of time. Sitting and kneeling are more often transitional postures between standing and lying, and are often held for relatively short periods of time. These postures are defined in Table P.1.

Postures can yield useful information either through relative amounts of time spent in normal postures, the number of changes between postures or the presence of abnormal postures.

Normal posture is often used in behavioural observations to give a general indication of the animal's state of arousal and/or level of comfort. Many **ethograms**, especially those used for the collection of **time budget** data, will include the separate postures either as behavioural classes or as modifiers (i.e. extra information that is added on to the original behaviour classification). Including posture in this way allows the time budget information to be analysed in greater detail if required. For example, instead of just having information on, say, time spent alert, we would now be able to distinguish between time spent standing alert and time spent lying alert.

Table P.1. Posture definitions.

Posture	Definition
Standing	Standing upright with soles of feet in contact with ground
Sitting	Sitting on buttocks with soles of front feet in contact with ground
Kneeling	Standing on rear feet but resting on carpus of front limbs
Lying sternally	Lying on sternum with belly in contact with ground
Lying laterally	Lying on side with belly exposed and limbs extended

The general classifications of normal posture are often used in comparison of systems, to determine treatment effects on such things as general activity and **resting behaviour**. For example, comparison of time budgets of pigs in a straw-bedded system versus a fully slatted, non-bedded system might show differences in all five posture classifications. Straw-bedded pigs may have increased time spent standing and lying laterally and decreased time spent sitting, kneeling and lying sternally. These differences may be due to the straw-based pigs spending greater amounts of time in active behaviours such as rooting and **exploratory behaviour**, and also more time sleeping in a position that demonstrates greater comfort. Of course, for these interpretations to be valid, additional behavioural elements would need to be collected together with the posture data.

Within a given system, the time spent in the various postures would fall within a fairly limited, 'normal' range. Within this range, there may be some degree of variation between individuals, but this variation would be small. Taking population means, however, may mask individuals within the system showing abnormal variation from that mean. An animal showing abnormal variation from the mean may well represent an animal that is encountering a **welfare** problem and, thus, posture data can be used to identify animals at risk. For example, an animal that is showing greater than normal time spent lying may be suffering from a clinical or subclinical illness. This may be a whole-body illness, causing lethargy or lassitude or it may be a localized infection or injury, such as a hoof or limb problem that is causing localized **pain** and **lameness**. In both examples, the animal is likely to spend less time carrying out active behaviour and thus spend a greater amount of time lying. Similarly, any animal spending different amounts of time to normal in other postures will also be worthy of investigation.

Posture changing

Other information that can be contained within time budget data, but may also be investigated separately, is that of posture changing or the number of transitions between postures. With scan sample data, the data contain only information on the posture that the animal is in at the instant of recording (**see: Measuring behaviour**). If an animal is, say, standing on two consecutive scans, it may mean that the animal has been standing for that whole time, but the animal may also have lain down and stood up again. To get the real incidence of posture-changing, continuous behavioural observation techniques would need to be used. However, counting the number of transitions in posture across scans can give a rough estimation of how much posture-changing the animal is carrying out. For example, say scan data show the following sequence:

Stand-stand-stand-lie laterally-lie laterally-lie sternally-sit-stand-stand

Looking for times when the posture is different between scans would show that in this sequence, there are a total of four postural transitions:

Stand—stand—stand—lie laterally—

lie laterally—lie sternally—sit—stand—stand

Comparisons of scan data and continuous data show that the number of postural transitions contained within scan data are very highly correlated to the actual number of posture changes carried out by the animal. Posture changing in itself is used as a measure of comfort. Ordinarily, many domestic animals may spend long periods of time in a single posture. Certainly, domestic carnivores and pigs show long periods of inactivity and/or **sleep**, and these periods contain long bouts within a single posture.

Domestic ruminants have much shorter bouts of activity and inactivity and therefore, usually, much shorter periods in a single posture. However, this difference notwithstanding, increased posture changing may well be indicative of increased restlessness, which may itself be caused by various external or internal factors. An example of an external factor is the example used earlier: comparison of pigs' behaviour in bedded and non-bedded pens may show that non-bedded pigs have an increased propensity to change posture more frequently, as a concrete **floor** is less comfortable than a straw-bedded floor. Conversely, sows in crates and cows in tie-stalls may show a decreased level of posture-changing behaviour relative to sows and cows in open pens. This is due to the physical constraints placed upon them, making transitions from standing to lying and lying to standing more difficult to achieve.

An example of an internal factor affecting posture changing is that of approaching **parturition**. As parturition nears, posture changing often increases markedly. In pigs, posture changing of the sow can also impact the survival of the young. Piglets are susceptible to being crushed by the sow when she lies down. Also, sows that carry out particularly high levels of posture changing during the immediate pre-parturition phase appear to be more likely to savage their piglets.

Abnormal posture can be used to describe modifications of the normal postures that are usually seen when the animal is undergoing challenge. The challenge may be such factors as illness, **disease**, pain or **fear**, and thus, the manifestation of abnormal behaviour can be an indicator that the animal is

P.483

having its welfare compromised. As already noted, abnormal amounts of time spent in postures may indicate problems. Modification of that posture may help to pinpoint the cause of the problem. An animal that is standing but only bearing weight on three limbs is an obvious example of an animal showing an abnormal posture - probably indicating a **lameness** issue with the raised limb that should be investigated.

Husbandry procedures such as tail docking (**see: Docking - tail**), **castration** and **mulesing** often induce abnormal postures indicative of the animal trying to decrease or cope with pain, such as 'statue standing' or lying on the side with limbs rigidly extended. In situations that induce fear, animals may become immobile and crouched or hunched, or adopt a posture that enables them to carry out defensive aggression.

Precautionary principle

The precautionary principle states that if an action might theoretically or logically cause harm, then those who wish to undertake this action have a greater moral responsibility to demonstrate good evidence that the action does not cause harm - i.e. action is not justified because of a lack of evidence of harm. For example, the precautionary principle would suggest that the wide-scale planting of genetically modified crops should not be undertaken until there is good evidence that they will not have a significant incidental impact on wild ecosystems.

Precocial

A state of neonatal maturity characterized by the organism being free-living and adopting behaviours that enable it to be in part independent of its parents. Generally considered to be the opposite of **altricial** development. Precocial bird and mammal neonates are fully covered by **feathers** or fur and are often able to thermoregulate effectively. In birds, hatchlings are self-feeding, albeit with parental supervision. In mammals, precocial offspring are active from birth but are reliant on maternal milk.

(DCD)

Predation

Predation is the act of an individual or group of individuals of one species (the predator) killing an animal of another species (the prey), with the intent of subsequently ingesting the killed animal. Within all ecosystems, predation is one of the most prominent interactions between species. The term predation is mostly used for an act of killing an animal, but it is also sometimes used to describe herbivory or the killing of seeds (seed predation). More generally, predation is a specific type of a broader set of interactions in which one species, in this case the predator, is positively affected and the other species, in this case the prey, is negatively affected. There are also cases where individuals kill and ingest members of the same species specifically termed **cannibalism**.

The stages of predation

Predation can be described as occurring across a series of stages: encounter, detection, recognition, attack, capture and consumption. Predators benefit from increasing the likelihood of each stage while the prey benefit from decreasing this probability. For example, wolves hunting elk search for (encounter, detection and recognition), stalk (attack) then run down (capture) an elk, whereas the elk seeks to avoid being seen and attempts to evade attack and capture by escaping. Predation is often studied from either the predator perspective or the prey perspective, and studies usually focus on one or a few stages.

Predator strategies

There is a wide array of strategies employed by predators to obtain prey. Predators can actively hunt, as individuals or groups, tracking prey (e.g. an owl hunting mice or lions hunting wildebeest) or can use ambush, sit-and-wait strategies or

‘surprise attacks’ (e.g. rattlesnakes hunting rodents by striking out from a hidden location). There are also other sit-and-wait strategies that use deceptive, trapping methods: spiders build webs to trap insects, deep-sea fish lure prey with bioluminescence appendages and several insect species mimic female cues of a prey species to lure males (aggressive mimicry). The sensory systems of predators are often well adapted to detect and recognize prey, especially prey specialists (those that feed on one or few prey species).

Prey strategies

There are equally as many strategies employed by prey to avoid predators. Prey can seek out areas that limit their exposure to predators either in terms of space (e.g. dense cover, rock crevices) or time (e.g. be active when their predator is not), become harder to detect or recognize as prey (e.g. cryptic coloration) or become harder to capture (e.g. speed, armour).

Predator and prey population dynamics

Predation can have a large effect on both predator and prey population dynamics. The simplest case is when one predator species feeds on one prey species. This generally results in both the predator and prey populations cycling relative to each other, with the predator population ‘lagging’ behind the prey population. The explanation for this centres on the time lag between predators capturing food and being able to use these resources to produce offspring. For example, when the prey is at high densities the predator’s population size (via increased survival and birth rate) should increase. This should cause the prey population to decline, which in turn makes it harder for

P.484

all predatory individuals to survive and reproduce. As the predator population declines, this should favour conditions for the prey population to increase, and so forth (the LotkaVolterra model).

Thus the peak in predator population size lags slightly behind that of the prey population size. In real ecosystems, food webs are usually more complicated (more predators and prey and thus alternative options), and data showing this tight predator-prey relationship are scarce. However, a classic example of such data is the Canadian lynx and snowshoe hare, where research shows a cyclic relationship.

Predation shapes phenotypes

For many prey species, predation is a major source of mortality and therefore is a strong agent of natural selection on prey phenotypes (a **phenotype** comprises the physical characteristics of an organism). Individuals of a prey species that are able to evade predation can pass heritable traits to the next generation, while successful predators can also pass heritable traits themselves to the next generation.

Over generations, predation can lead to the evolution of many forms of anti-predator mechanisms (behavioural, morphological and/or physiological) and, in turn, the precision of predator strategies and these traits are said to be ‘co-evolved’ traits. One example is a co-evolutionary arms race where successful predators and prey are both selected to improve survival, but the adaptations of the other species tend to offset any change in survival. For example, cheetahs that tend to be faster survive and reproduce better; however, because the cheetahs tend to be faster, the gazelles that tend to survive and reproduce are also faster. This tends to lead to both the cheetah and the gazelle becoming faster. Another example is toxins in prey western newts and resistance to these toxins in predator garter snakes, where over evolutionary time the newts have become more toxic, while the snakes have better resistance.

Predation and domestic animals

Domestic animals (from livestock to dogs) are not considered part of most ecosystems, but they are not immune to predation. Wolves, coyotes, wild cats and birds of prey are very capable of predating on domestic livestock, fowl, etc. In some cases, domestic animals have essentially lost the skills needed to evade predation (or ancestors of these domestic animals may never have encountered such predators), so they are ‘easy’ prey. In addition, some species of domestic animals (especially cats) can be significant predators in their local ecosystem. This may be viewed as beneficial by people when it is directed towards pest species (**see also: Pest control - ethics of and Pest species - welfare of**), but in other situations it is of greater concern because it may devastate indigenous fauna, or at least have a significant impact on local levels of wildlife.

Predator avoidance

Predator avoidance involves behaviour, morphology or physiology that reduces an individual's probability of encountering, being detected, recognized, attacked, captured and/or consumed by a predator - collectively reducing predation risk. Most animal species are prey to other animals, and this predation is a major source of natural selection. This has led to the evolution of a vast array of anti-predator mechanisms.

Stages of predator-prey interactions

Predation

Predation be described as occurring across a series of stages: encounter, detection, recognition, attack, capture and consumption. Predators benefit from increasing the likelihood of each stage, while the prey benefit from decreasing this probability. Depending on the particular stage of predation, there are many different forms of anti-predator mechanisms prey can use to evade their predators.

Reducing encounter probability

Prey can reduce the probability of encountering a predator by adjusting their spatial and temporal activity patterns. Thus, they can avoid dangerous areas or times of the day (or night). For example, certain prey species may have become **nocturnal** to avoid diurnal predators, or vice versa.

Reducing detection

To decrease the chance of being detected by a predator, prey species can be cryptic: morphologically by blending into their background using camouflage (e.g. cryptic patterns, colours), or behaviourally by becoming motionless or moving with the background environment. For example, walking stick insects not only blend into their background but some species also move to match vegetation movement.

Reducing recognition

Mimicry can be used by prey species to 'dupe' predators by reducing the prey's probability of being recognized. Prey can mimic organisms that are noxious, toxic and/or unpalatable (Batesian mimicry) to prevent predation, such as the classic example of the Viceroy butterfly mimicking the wing colour patterns of the unpalatable Monarch butterfly. In addition to visual cues, mimicry also occurs in other sensory modalities: the hiss of burrowing owls sounds like the rattle of a rattlesnake, and may keep potential mammalian predators out of their burrows (acoustic mimicry).

Reducing attack

Prey can deter an attacking predator. Morphologically, prey may threaten predators with spines, horns or other external weapons (e.g. rhinoceros' horns). Prey can also use startle behaviours (flashing wings, making a loud noise, releasing pungent odours) that confuse, distract or deter predators. Predators may also decide not to attack a prey animal that has

performed a 'pursuit deterrence' behaviour. Pursuit deterrence involves a prey animal communicating to the predator that it has been spotted and/or that the prey will probably outrun the attack (escape ability). For example, several ungulate species 'stot' (jump straight up into the air) when a predator is spotted and it is suggested that stotting deters the predator from continuing or beginning an attack.

Evading capture

To evade capture prey can simply attempt escaping and/or take refuge in a structure the predator cannot enter or climb (e.g. rock crevices or trees). Prey can also avoid capture using their bodies, such as turtles and crustaceans retreating into their shells or prey that can roll up into a ball, protecting themselves with armour (e.g. armadillos). Prey can also use defensive behaviour such as clawing, biting and/or stinging to injure the predator. Some species can 'drop' their limbs (termed tail autotomy or limb autotomy) to escape capture (e.g. some lizard, rodent, insect and crustacean species).

Evading consumption

Consumption by a predator can be avoided by several mechanisms, including toxicity/unpalatability. Other potential mechanisms are death feigning and fear screams. Although not completely proved to be anti-predator behaviours, animals that feign death (e.g. **tonic immobility**) or scream during the capture stage may avoid being consumed by confusing or distracting the predator.

Grouping to avoid predators

Prey species can avoid predation by forming permanent or temporary groups with **conspecifics** (members of the same species) and/or **heterospecifics** (members of other species). Individuals benefit from joining groups for several reasons (**see: Grouping**).

Increased vigilance

Prey animals can increase the probability of detecting a predator by being in a group, sometimes called the 'many eyes' hypothesis. For example, individual sparrows in flocks spend less time being vigilant (head up) because, with more flock members, there is a greater probability that some other bird(s) is looking up to detect predators.

'Selfish herd' or 'Dilution effect'

These hypotheses assume that an individual in a group has a decreased probability of being captured, because the predator has more prey animals from which to select in the group. Schools of fish may make it difficult for predators to 'lock into' one individual to capture, and schooling reduces the chance of an individual fish being caught.

Confusion effect

When a predator attacks a group, the general confusion of the prey animals escaping may interfere with the predator's ability to track and capture an individual.

Warning signals

Prey species can benefit from perceiving and responding to warning signals (acoustic alarm calls, visual or chemical signals - **see also: Signal**) produced by conspecifics or heterospecifics. Individuals in close enough proximity to hear, see or smell the warning signal are often related (kin) to the signaller and can benefit from a seemingly altruistic behaviour (**see also: Altruism; Kinship**).

Mobbing

Animals in groups or individuals can mob a predator and decrease the predator's chances of a successful kill. Mobbing occurs when prey animals closely approach a predator (most often when it is not hunting) and engage it by chasing it, striking at it or performing other antagonizing behaviour. Predation risk may be low in mobbing situations, as most of the predators being mobbed rely on surprise attacks to capture prey. Several examples include monkey troops mobbing snakes, birds

mobbing hawks and seals mobbing sharks. An impressive example is that of California ground squirrels that will closely approach and kick dust at rattlesnakes.

Evolution and development of anti-predator behaviour

Innate versus learned

Although a false dichotomy, anti-predator behaviour is sometimes categorized as innate or learned. Some behaviour can appear 'innate' because individuals successfully evade predation prior to extensive experience with the predators; however, it is difficult to prove that no experience was necessary for those behaviours to develop. Learned behaviour may be acquired through individual experience or can be obtained through social learning. In a classic study of **social learning**, researchers were able to make birds react with mobbing behaviour towards a plastic jug because it was paired with the mobbing call of a conspecific.

Predator naivety

Predator-naïve prey (i.e. prey that do not recognize and respond appropriately to predators) may or may not be capable of learning about novel or ancient predators. Novel predators can arise by invasion or introduction to an area where the predator has never existed (e.g. **feral** cats and foxes in Australia), and ancient predators are those that the prey species have not been in contact with for many generations (e.g. wolves reintroduced in North America). For example, although moose have not been in contact with wolves for hundreds of years, they are able to respond appropriately after experiencing predation and predator cues. However, wallabies are sometimes incapable of escaping or learning about novel prey such as feral cats. Domesticated animals also sometimes lose their antipredator behaviours, making them susceptible to predators. This may have occurred through artificial selection or due to lack of a persistent exposure to predators over time.

P.486

Predator control

Predator control is perhaps one of the most controversial issues in **wildlife management**, involving the active management and limiting of predator populations through human intervention. In natural systems, predators play an important role in ecosystems and can regulate prey populations. However, predator-prey dynamics can be unstable in disturbed systems, with increased predation driving prey species to **extinction** in certain situations. For example, exotic predators such as the black rat introduced on to islands have caused the extinction of many rare avian species. Thus predator control may be deemed necessary to protect threatened and endangered species. Habitat changes can also lead to increases in the number of native predators.

Agricultural practices, including sheep/cattle ranching and poultry farms, along with wildlife refuges, may inadvertently increase the carrying capacity for predators and create higher mortality losses for prey populations. In fact, preventing economic losses is one of the primary reasons for predator control. Besides predation on livestock, predators may also compete with humans for game species or pose a threat to human health or safety. Because of these human-wildlife conflicts, predator control programmes have been created to reduce agricultural losses, increase game species numbers, minimize risk to humans and/or assist in the recovery of **endangered species**.

The theory of predator control is based on the negative relationship between predator and prey abundance, with increased prey survivorship with fewer predators. Several different lethal and non-lethal techniques have been employed to remove predators, including trapping, translocation, ground and aerial shooting, poisons, snares and sterilization (**see: Pest control - ethics of**). However, depredation management is not always effective due to the complexity of predator behaviour and ecological interactions among predators and prey. Predator control has threatened the persistence of some predator species, while others have been extremely resilient to control efforts. Removing top predators also can create **trophic cascades** and **mesopredator** release, impacting non-target species. Consequently understanding the ecology and behaviour of predators is as critical as knowing the benefits and costs of predator control.

Preening

Feathers are critical not only to bird flight but also for thermoregulation, and can be important in other aspects of avian biology, e.g. reproductive success. As a result, feathers require regular maintenance to ensure that they are in good condition and so serve their various functions efficiently. Preening with the beak, or sometimes the feet, is one of a range of behaviours that serves to maintain the condition of the feathers; others include **dust bathing**. In that it involves care of the integument it is analogous to **grooming** behaviour. Flight feathers only function efficiently if they form a surface to resist the air, and so preening ensures that the mutual attachment of barbules is as continuous as possible. Care of down and other feathers covering the body is important in trapping a layer of air close to the skin and so maximizing the efficiency of **thermoregulation**. Preening is most commonly performed by individuals upon their own feathers, but mutual preening can be a key component in the formation of a pair bond in some species, e.g. parrots.

Preening is seen as an important behaviour of birds, albeit forming a small percentage of their **time budgets**. Depriving a bird of the ability to preen normally is considered by many as being a welfare issue. The act of tending feathers is seen as a precursor of other more deleterious behaviours. Selfplucking, or chewing of feathers, is interpreted as an extension of normal preening behaviour, but taken to an extreme when the individual bird is in a stressful situation. Typically, birds maintained within poor captive conditions, or deprived of performing some other key component of their behavioural repertoire, develop behaviours that lead to damage of the feathers either on their own body or on their companions, which are resistant to behaviour modification even after the stressors are removed.

(DCD)

Preference

Animals show preferences in their daily decision making, choosing between available resources (such as food sources, potential territories or mating partners) and behaviours. **Ethology** and **behaviour ecology** studies (**see: Optimal foraging**) support the assumption that such decision-making mechanisms are the evolutionary product of natural selection, i.e. through **evolution**, animals' preferences have been shaped so that the animals will look for and prefer situations and resources which promote their survival. Equally, they would be motivated to avoid environments detrimental to welfare.

Preference studies as an instrument in animal welfare research were first proposed by the ethologist W.H. Thorpe in his appendix to the 1965 Brambell Committee Report. The first preference experiment also addressed a question discussed in the **Brambell Report - flooring** material for laying hens in cages. By placing hens in a pen with two compartments, each with a different flooring and studying how much time the birds spent in each of these compartments, Hughes and Black (1973) could demonstrate that hens did not show any strong preference away from the 'chicken wire' thought unsuitable by the Brambell committee.

The hen cage floor example illustrates the essential value of preference studies and the consumer demand studies (**see: Economics of behaviour**) that have developed from them: that these tests offer a way of asking the animals directly rather than relying on human judgement of what might or might not be good for animal welfare. However, as experience has shown, the matter is somewhat less straightforward than was initially believed.

The most common design of a preference test is similar to that described above: an experimental set-up with several compartments containing different resources, where animals can choose where to stay and where their choice can be monitored. Because preference can depend on time of day, internal state and what activities the animal is carrying out, it is important that the set-up permits monitoring the behaviour of the animal over extended periods of several days. Such

monitoring can be automated with the help of video equipment and automatic event recorders such as a photo beam being broken each time an animal passes from one compartment to the other.

P.487

Even the most carefully designed preference experiment will, however, only give information about whether one resource is preferred over another, and tell us nothing about how strong this preference is. Experiments measuring preference strength have come to play an important role in animal welfare research. The underlying assumption is that the more an animal prefers a resource, the more its welfare will be affected by frustrating access to this resource. However, some caution is needed in assuming a direct link between motivation strength and welfare, as there may be cases when animals (including humans) are strongly motivated to access resources that are not good for their long-term welfare.

Strength of preference can be measured by making access to a resource costly. The cost can consist of a task that the animal has to perform, such as making a number of lever pushes or button presses during a given time. This method is described as operant testing (**see: Operant test**). Because the operant task is usually artificial, some researchers advocate the obstruction method, where the animal has to make its way through an obstruction, such as a narrow gateway, a water bath or a weighted door. Independent of the type of cost, in the simplest approach the animal is asked to pay a single predetermined cost to obtain access to the resource and, if it is found willing to pay that cost, it is assumed to be motivated to use the resource. It is possible to refine this measure if the cost can be increased in a stepwise or continuous manner so that the motivation can be quantified.

The British biologist Marian Dawkins has been an important driving force behind the introduction and development of operant testing as an instrument in animal research. She originally suggested that an unknown **motivation** could be quantified by titrating it against the motivation for a resource for which motivation was well known and could be easily manipulated, such as feeding motivation. This approach was further refined by bringing in consumer demand theory from economics research. In consumer demand studies, the demand for a resource is studied when the cost for gaining access to it is increased. The demand (the amount of the resource obtained) is plotted on the y-axis against the cost on the x-axis. The slope of the resulting curve can be used as a measure of the demand strength.

Commodities for which a given percentage increase in price results in a decrease in the quantity demanded are said to have *elastic demand* and are sometimes called luxuries; those for which a given percentage increase in price results in little change in the quantity demanded are said to have *inelastic demand* and may be called necessities ... Elasticity of demand is a key concept for the study of animal welfare ... because it shows how important different environments or commodities are to the animals themselves.

--(Dawkins, 1990)

An alternative approach to make resource access more costly is through restricting the time an animal has available by changing the light schedule so that the active period is shortened. The assumption is that animals will persist in performing the most important behaviour patterns, whereas less essential behaviours are strongly reduced or disappear completely when the animal has less time.

There are a number of factors that may affect the outcome and the possibility to extrapolate outside the test situation, which ought to be taken into account in designing the study. These include differences in preferences between animals (depending on sex, breed, age, reproductive state, etc.), previous experience with any of the resources, cues from resources, duration of access to resources as well as overall time or energy budgets. Moreover, animal choice and preferences may be affected by how many options are available and whether they are independent or whether some of these can substitute for or complement each other. There has been much discussion of how these issues impact on the conclusions that can be drawn when using preference tests for welfare recommendations.

Preparedness

The concept of biological preparedness proposes that different species (or possibly populations within a species that have been selected for a given trait) have differing propensities to learn certain types of association or that certain types of association are biologically easier to form. It is suggested that natural and human **selection** have favoured biases in the types of association that can be formed. As such, the concept of biological preparedness opposes the universal generality of the Laws of Association, proposed by early behaviourists, who suggested that external relationships are all important in the learning and that all associations are equipotent, i.e. have equal probability of being formed on the basis of the equivalence in relation to the Laws of Association (**see: Conditioning - types of**).

Biological preparedness suggests that different species may be predisposed to develop **fear** in relation to stimuli that are of evolutionary significance, or perhaps different breeds of animal selected for different functions. For example, noise fears are less common in the typical gun dog breeds. However, biological preparedness also implies that a given species may find it easier to learn one type of association over another - for example, an **aversion** to a given food may be more readily made with the flavour of a food than with a similarly contingent visual stimulus. It might be argued that the concept of biological preparedness extends also to the predisposition to learn certain associations at certain times (**sensitive phases**), which may be of phylogenetic adaptive significance - for

P.488

example, children appear much more sensitive to learning to fear animals around the age of three, when historically they would be much more mobile and independent.

Other phenomena that it has been suggested can be explained by biological preparedness include: (i) a greater resistance to extinction of certain associations over others; and (ii) the ability to form certain associations without manifest attention to them. However, some argue that other explanations are preferable in understanding these phenomena.

Problem behaviour

Problem behaviour is a personal rather than a physical construct, as it describes any behaviour that is problematic for the individual reporting it. The problem is not the animal's behaviour per se, but rather the problem it poses to the reporter. Thus the problem may be resolved by altering the understanding, attitude or opinion of the reporter without necessarily effecting any change in the behaviour of the performer. For example, the behaviour of a cat in **oestrus**, which wails and appears to a naive owner to be in **pain** may be a problem until it is explained that this is the normal behaviour of the species. The term does not imply that the behaviour is **maladaptive**, nor necessarily associated with poor **welfare**. Although some consider the term to be synonymous with behaviour disorder or **abnormal** behaviour, the former term, in particular, implies that the behaviour is not structured appropriately and reflects a medicalization of the construct (as has been applied in human psychiatry in relation to problem human behaviour), which has given rise to numerous misconceptions in the field (see Mills, 2003).

While some behaviour problems may be disorders, such as panic disorders where the response is out of proportion to the potential threat and interferes with normal functioning, this does not apply to perhaps the majority of problem behaviours seen in clinical practice, such as **urine marking** and scratching in the cat, most causes of **aggression** and barking in the dog or bucking in response to back pain in the horse.

Broadly speaking problem behaviour may be derived from one of three types of action: (i) those that have adaptive value within the species but are inconvenient for the keeper (these are adaptive behaviours); (ii) attempts to behave in an adaptive way in an environment to which complete adaptation is not possible (these may be considered maladaptive behaviours); and, finally, (iii) expressions of direct disruption of the nervous system (i.e. the neural basis has no functional value in any context and so is truly malfunctional). Accordingly, there is no objectively consistent or defining feature of a problem behaviour but, once its broader social context is recognized, so too are the full range of approaches to its scientific study and resolution. This refocuses attention away from just the individual performing the behaviour on to a broader perspective that extends to the physical and social environment to which the animal is responding. The study of problem behaviour is therefore a multidisciplinary challenge.

Procedural knowledge

Procedural **knowledge** refers to the state of knowing 'how' to do something. Procedural knowledge is often contrasted with declarative knowledge (also referred to as descriptive knowledge, factual knowledge or propositional knowledge), which describes factual knowledge. Thus a trainer may know how to get a dog to sit for a treat (procedural knowledge), but may not know much about the reasons why this works (declarative knowledge). Declarative knowledge forms the basis of thinking about something, and may be further divided into episodic knowledge (knowing about the context of something) and semantic knowledge (knowing the meaning of something, but not in a personal way). The extent to which non-human animals are capable of having different forms of knowledge is debated widely; however, the possession of knowledge does not equate to either **awareness** of that knowledge or **consciousness**.

(DSM)

Proceptivity

Proceptivity refers to the behaviour carried out by the female that enhances the creation, maintenance and escalation of a sexual interaction (**see: Sexual behaviour**). It specifically refers to the pre-consummatory, that is, pre-ejaculatory, phase of a sexual interaction. There is evidence to suggest that **oestrogen** and adrenal **androgens** play an important part in increasing proceptivity.

Production animal diseases

Diseases can be defined as conditions of organisms that impair body functions and are associated with certain physical signs. Animal production systems tend to show a higher prevalence of certain diseases associated with increased productivity. The term production disease is often used to refer to non-infectious conditions such as metabolic and management problems, typically associated directly with the high productivity demands of these systems, while the broader term 'production-related disease' may be used to include secondary problems, such as infertility and a range of infectious diseases to which these animals are particularly prone because of their circumstances.

There are a number of additional factors that contribute to the high occurrence of different forms of disease in these animals. For example, animals in production systems tend to have similar **genotypes**, and since many of these conditions have a substantial genetic component, they are more likely to be widespread due to the widespread prevalence of genetic risk factors in the less diverse population. Prevention may therefore require selective breeding, but this may compromise productivity. These animals are usually fed similar concentrate feed rations and are often kept in close contact with their faeces. Additionally, different production stages usually happen at different sites and the animals are moved together in large groups. These factors can all contribute to large outbreaks of

P.489

certain diseases and the ease with which disease can spread through groups of animals. The multifactorial nature of these problems means that their management should also be multifactorial and potentially multidisciplinary, with consideration given to strategies aimed at both the individual and population level of the problem. Examples of some of the more common production diseases are discussed briefly below (see also specific individual entries where appropriate).

Ascites

This condition is often found in broiler **chickens** and is a major cause of **mortality** in these animals. It is an accumulation of fluid in the peritoneal cavity. The most common cause is increased back pressure in the venous system (pulmonary hypertension) associated with right ventricular cardiac failure. This problem arises because selection for high growth rate in these birds means that the physical growth of some individuals exceeds the capacity of the lungs to provide sufficient oxygenated blood. Higher growth rate demands a higher level of nutrients and oxygen, which is provided in part by increasing **blood pressure**, which results in chronic hypertension.

Challenges that increase cardiac demand may trigger a bout of ascites and associated mortality as cardiac capacity is exceeded. For example, exposing animals to a lower environmental temperature (**see: Critical temperature**) for a short period may increase metabolic demand for thermo regulatory processes and trigger the problem. Similarly, any problem that reduces the efficiency of oxygenation, ranging from mild infectious respiratory diseases to poor air quality, may result in a compensatory cardiac response that serves to try to increase blood flow through the lungs, but which may ultimately result in cardiac failure. Although the condition can be treated theoretically with drugs, this is uneconomic and often impractical for animals destined for human consumption. Reducing the birds' metabolic oxygen requirement by slowing growth or reducing feed can prevent ascites.

Mastitis

Mastitis is very common in lactating production animals, such as cows, sows, mares, goats and ewes. It is the **inflammation** of the mammary gland(s) associated with bacterial infection. The milk will often be visibly abnormal, e.g. in colour, or have clots, and the udder may swell, be red and hot and be painful to the touch. Risk factors for developing mastitis include poor sanitary conditions, trauma inflicted by offspring and systemic infection.

Lameness

Lameness is the third most economically important problem in dairy cattle (mastitis and infertility being more economically important). Lameness is also commonly found in **sheep**, **goats**, **pigs** and broiler chickens. The incidence of lameness has increased since the late 1980s. Production animals housed on concrete floors or which are unable to get appropriate exercise often show some degree of lameness. Management aimed at reducing abrasion and contact with faeces, or prolonged soaking of the feet, foot trimming and foot bathing are all important treatment measures for managing the condition.

Ruminal acidosis

Also known as metabolic acidosis or milk acidosis, this is a common disease found in ruminants since grain and concentrate feeding became a widespread practice associated with a demand for higher productivity. The pH of the rumen becomes more acidic due to increased starch intake, lack of forage and associated chewing and rumination. It consistently causes anorexia, and movement of feed through the rumen slows and may even stop. Faeces will be loose and dehydration will occur. Ruminal acidosis is a predisposing factor for many other problems in cattle fed high-grain diets, such as **laminitis**, sudden death syndrome and liver abscesses. Its exact relationship with another production disease, ketosis (acetonemia), is unclear.

Ketosis arises as a result of the mobilization of fat reserves to provide glucose due to a negative energy balance with the diet. The condition is most commonly seen in early **lactation** when demand is at its highest. Fatty acids are converted by the liver to ketones, which, if allowed to accumulate, become toxic, suppressing appetite and exacerbating the problem further. It is possible that the anorexia associated with ruminal acidosis may precipitate ketosis, or vice versa.

Hypocalcaemia

Another production condition of lactation that is particularly prevalent in mature cows is hypocalcaemia, resulting from the initial demand for calcium in the milk at the onset of lactation depleting the mobile reserves in the body. Hence the condition is also known as milk fever, or parturient paresis, in dairy cows. Given the importance of calcium to the activity of muscle cells, it presents as an afebrile flaccid paralysis around the time of **parturition** that can ultimately lead to heart muscle failure and death.

Hypomagnesaemia

Also known as grass tetany or staggers, this condition may occur in association with hypocalcaemia or independently, and arises as a result of a lack of magnesium uptake, particularly when much is lost in the milk during lactation. It is important to identify or eliminate its co-occurrence, as treatment resulting in excessive magnesium may be equally dangerous. Typically, the animal is more excitable and twitchy when hypomagnesaemia is involved. The problem can arise because the animal is feeding on species of herbage that are low in magnesium, or on lush herbage that is naturally lower in this mineral. Alternatively, the condition may arise secondarily to some cause of anorexia or reduced appetite. The use of nitrogen and potassium fertilizers on pasture may increase the risk by both encouraging a flush of lush grass and because these minerals reduce magnesium uptake from the rumen.

Diarrhoea (scours)

Diarrhoea is a condition commonly found in young production animals and can have a variety of different causes. In calves, those fed large amounts of milk or inappropriately formulated milk replacers produce a large volume of loose faeces. Piglets may contract a bacterial infection characterized by watery or greasy, yellow-white diarrhoea. Piglets may appear weak, dehydrated and undersized, weight gains may be depressed and individuals sometimes die. A contributing factor to

P.490

mortality is that piglets become covered with diarrhoeic faeces and stay damp.

Other conditions

There is also a wide range of highly infectious diseases of relevance to production animals, which, while not associated directly with productivity (and so not typically considered production-related disease), because of certain factors associated with productivity such as stocking density, especially in the case of poultry, or movement policies, may be of particular concern to those working with production animals. These include conditions such as Marek's disease, a common paralysing and often fatal viral disease of domestic poultry. The virus matures in the feather follicle and is released into the environment with dust or dander. Newcastle disease is another common viral disease of domestic poultry and many other bird species. It usually presents as a respiratory disease, but infected birds can also show depression, nervous manifestations or diarrhoea. The virus is shed and easily transferred through respiration and in the faeces. Infection may be introduced by wild birds, and control for both these measures and similar conditions is through biosecurity, an all-in/all-out population policy and vaccination.

While production diseases tend to be thought of in relation to high-productivity, intensive systems, it is important to realize that less intensive systems, such as **organic farming** systems, may be associated with their own range of production

diseases associated with the particular husbandry practices, e.g. endoparasitic problems if anthelmintics are not used and pasture management is inappropriate.

Progesterone

Progesterone is a C-21 **steroid hormone** belonging to the hormone class progestogens, which have hydrophobic properties. Progesterone is involved in the female oestrous cycle (**see: Oestrus**) and during pregnancy, its main function being to maintain gestation.

Progesterone is mainly produced in the **adrenal** cortex. Acetyl-Coenzyme A is a side-chain cleaving enzyme that cleaves the initial substrate cholesterol to form pregnenolone, from which progesterone is synthesized. Progesterone can then take part in two different pathways. It can either be used in the synthesis of **corticosteroids** through the synthesis of deoxycorticosterone, corticosterone, cortisol or aldosterone; if the progesterone takes part in the sex steroid pathway, it is then a precursor to 17- α hydroxyprogesterone, androstenedione, **testosterone**, estradiol-17 β and estrone (**see: Oestrogen**). Progesterone is synthesized in the corpus luteum after ovulation, the placenta during pregnancy, and the **brain**. The placenta uses maternal cholesterol to produce progesterone. The majority of placental progesterone enters the circulation of the mother, and the rest enters the fetal circulation and is utilized as a substrate for fetal corticosteroids.

During the early follicular phase (early growth phase of the follicle) of the oestrous cycle, **lutening hormone** (LH) and **follicle-stimulating hormone** (FSH) are at medium levels and oestrogen and progesterone levels are low. In the late follicular stage, there is further growth of the follicle.

Concentrations of LH and FSH remain similar to that of the early follicular phase; during this time oestrogen levels increase and progesterone levels remain low. The rise in oestrogen causes a rapid increase in LH and FSH, which stimulate ovulation to occur. During the luteal phase, the corpus luteum develops and, with this, oestrogen and progesterone levels increase, these high levels of progesterone and oestrogen having a negative feedback on the **pituitary gland**, thus inhibiting the release of LH and FSH.

If fertilization does not occur, the corpus luteum regresses sooner or later, depending on the species, and there is a reduction in the levels of oestrogen and progesterone. There is no longer a negative feedback effect on the pituitary, and LH and FSH increase to the levels they were at during the early follicular phase. However, if fertilization occurs, progesterone aids implantation of the blastocyst by reducing the maternal immune response so that there is acceptance of the pregnancy. Progesterone helps to maintain pregnancy and remains at high levels until the placenta is expelled during **parturition**. The rapid decrease in progesterone after parturition is followed by a rapid increase in **prolactin**, which is involved in milk synthesis.

Progesterone receptors are present in mammary tissue in many different species. It has been suggested that progesterone stimulates ductal growth and lobulalveolar development in prepubertal mice. In dairy cows, a mechanism has been suggested that, during late pregnancy, progesterone has a role in mammary development by promoting the survival of mammary epithelial cells by inhibiting apoptosis. Progesterone's inhibitory effect of apoptosis of murine mammary epithelial cells help to prolong lactation in these mice. The mechanism of how progesterone inhibits apoptosis is not clear but it is thought that progesterone inhibits matrix proteinases which, in turn, would prevent the degradation of basement membrane and, as a result, prevent mammary apoptosis.

In lambs, it has been suggested that progesterone and its metabolites suppress fetal arousal behaviour. In studies where progesterone or its metabolites were injected into fetal circulation, it was found that fetal electrocorticogram, electrooculogram and **electroencephalogram** activities, behaviour **arousal** and breathing movements were reduced. During the last days of pregnancy, there is a decrease in progesterone in placental and fetal circulations. This reduces the inhibitory effects that progesterone has on behaviour arousal, thus facilitating a vigorous behavioural phenotype following parturition of the lamb and increasing the survivability of the newborn.

It has been suggested that adrenal progesterone may be a sensitive indicator of **pain** in some contexts. Bulls given **anaesthesia** before **electroejaculation** have lower levels of progesterone than bulls that were not given anaesthesia. Progesterone and its metabolites are thought to act as a natural anaesthetic in animals and humans. A mechanism suggested for this is that progesterone interacts with GABA_A receptors, thus increasing the binding of the neurotransmitter

GABA. One of GABA's roles is to inhibit pathways of the **central nervous system** and, as a result, help desensitize that system to painful stimuli.

Progesterone is also a neurosteroid. As a neurosteroid, progesterone plays a neuroprotective role and is implicated in

P.491

myelination and synaptic function. In this capacity it is suggested that progesterone may be involved in **memory** and **cognition**. Progesterone plays a vital role in keeping individuals healthy. It is a thermogenic compound involved in raising core temperature. Progesterone is also involved in reducing muscle spasm, and the widening of bronchi and mucus regulation.

Prolactin

Prolactin is a phylogenetically old hormone. It is a peptide consisting of about 190 amino acids (varies between species) and it is secreted from the anterior **pituitary gland**, and during gestation also from the placenta. It is controlled by a complex array of excitatory and inhibitory factors involving **serotonin** as a stimulatory factor and **dopamine**, **epinephrine** and **norepinephrine** as inhibitory factors (although the latter two substances can also be stimulatory in some circumstances). There is a circannual and **diurnal rhythm** in many species, with longer days stimulating release and release levels being higher at night than during the day. Prolactin is named after its promotion of **lactation** in female mammals, but it has many additional functions. In relation to behaviour, its primary involvement is in **sexual behaviour** and **parental behaviour**. In relation to animal welfare, prolactin is relevant as a **stress** measure.

Prolactin plays an important role in lactation of mammals. It is involved in the development of the mammary gland along with **steroid** and **growth hormones**, and in the initiation of milk production along with **oestrogen**, **glucocorticoids** and **insulin**. Prolactin is also very important in the maintenance of milk production. Studies have shown that milk production is reduced when a prolactin inhibitor is administered either prepartum or during established lactation. Suckling causes a dramatic increase in prolactin, and in cows there is a correlation between the prolactin level and milk yield.

In some species, prolactin is implicated in prepartum nest building in the female (**see: Nesting behaviour**). An example of this is the rabbit doe, which builds a nest of grass that she lines with her own fur. The fur loosens through pregnancy so that it can easily be removed at the time of nesting. This loosening depends on hormonal changes. The primary change is release of prolactin in response to an increased oestrogen/**progesterone** ratio at the end of pregnancy. It has also been suggested that prolactin is responsible for initiating prepartum nest building in sows, because there usually is a concurrent rise in nesting activity and prolactin as parturition approaches. However, studies have shown that nesting can occur without the rise in prolactin, and the exact hormonal regulation of nesting in pigs remains to be determined.

Maternal behaviour and care for the neonates involves prolactin. In rats, it has been found that infusion of prolactin in steroid-primed rats induces maternal behaviour very quickly. In hamsters, decreased prolactin levels during pregnancy induced by a prolactin inhibitor also impaired maternal care. There was reduced maternal **aggression** toward male intruders, increased aggression toward pups, disturbed pup retrieval behaviour and increased maternal **cannibalism** (**see: Infanticide**). Similarly, in mice with the prolactin receptor gene deleted, maternal behaviour was disturbed, indicating that the prolactin receptor is important in mediating maternal behaviour.

Prolactin also seems to be related to paternal behaviour in species that display this behaviour. In the males, prolactin is elevated through pregnancy and remains elevated after birth. In mice, comparison of unmated males and expectant fathers showed that most expectant fathers performed paternal behaviour, whereas unmated males did not. In expectant fathers, prolactin levels were significantly higher than in unmated males – they were in fact comparable to those of the expectant mothers. In gerbils there seem to be two male strategies. Prolactin and **testosterone** levels rise during pregnancy, and testosterone then either drops at the birth of the pups or it remains elevated. In the former case the males behave paternally and, in the latter case, they pursue additional copulations. Similar results have been found for common marmosets and dwarf hamsters. It should be noted, however, that these studies are correlational and therefore merely suggestive of a causal relationship.

The role of prolactin in parental behaviour in birds, i.e. broodiness, incubation of eggs and feeding of young, has been studied in many species of birds. The initiation of the breeding cycle is caused by annual change in daylight stimulating prolactin production. Further increase in centrally acting prolactin after oestrogen and progesterone priming induces nesting and incubation behaviour. Prolactin rises to a peak during the incubation phase, where the pituitary also shows enhanced responsiveness. In some species, a brood patch develops on the breast to improve heat transfer from the female to the eggs. Prolactin acts together with ovarian steroids to increase vascularization and **feather** loss in the patch. Stimulation of the brood patch by the eggs or a familiar nest site maintains the high levels of prolactin release. In photorefractory bird species, prolactin is involved in autumnal gonadal regression. Prolactin is not considered to cause

P.492

photorefractoriness, but the seasonal peak in prolactin may serve to fine-tune the timing of the end of the breeding season.

In males, sexual stimulation (e.g. exposure of a stallion to an oestrous mare or ejaculation in the bull) produces a rapid prolactin release, with fast decline after mating. Sexual behaviour can also be induced by short-term, moderate prolactin administration. In contrast, prolonged treatment or higher dosages decrease sexual behaviour in males. Hence, rats receiving a single, centrally administered prolactin dose showed increased sexual activity, but a long-term treatment had the opposite effect. Similarly, in rams given a prolactin inhibitor, frequencies of mounting and mounting attempts were reduced. An association between low **libido** and increased prolactin levels has been found in several other species (e.g. rats, mice and bulls). The inhibition may occur through either dopaminergic **neuron(e)s** and through inhibition of spinal reflexes and neuromuscular connections controlling erection and ejaculation or effects on release of steroid hormones from the **gonads**. Similar paradoxical effects of prolactin have been found with female rats, with low, short-term doses increasing **lordosis** and higher, longer-term doses inhibiting it.

Prolactin can be used as a stress measure. Plasma levels increase within a few minutes in response to stressful stimuli in many species, although the relationship is not straightforward. For example, prolactin levels in sheep increased in response to **restraint, transport, isolation** and/or **novelty**. Similar findings have been made in pigs. However in rescue dogs, following neutering, a reduction in prolactin has been recorded, with no effect on cortisol with adequate analgesia, and it has been suggested that this may reflect an interaction with prior sensitization of dopamine pathways as a result of chronic **frustration**. Dogs with generalized **anxiety** are reported to have raised levels of prolactin, but those with phobias or mild anxiety appear to have normal levels. However, in pigs and horses, prolactin levels rose in response to a repeated painful **stressor**, i.e. nose snaring in the pig and twitching in the horse. The rise in prolactin may be due to release of **β-endorphin**, which decreases levels of dopamine acting to inhibit prolactin release, as well as to hormonally induced prolactin release. The role of prolactin in the stress response is not clear, but it has been suggested as modulating immune function and

suppressing **reproduction** temporarily. Prolactin enhances the responsiveness of the **immune system** by stimulating **cytokine** release from helper T-cells. It inhibits reproduction by interaction with the hypothalamic-pituitary-gonadal axis.

Prolactin-inhibiting factor (PIF)

Also known as prolactin-inhibiting hormone (PIH) and prolactostatin. Unlike other pituitary hormones, **prolactin** release is largely under inhibitory control, so if the connection between the **hypothalamus** and **pituitary gland** is severed, circulating levels of prolactin will increase, while the levels of other pituitary hormones fall. This phenomenon was observed before prolactin-inhibiting factor was identified, but was used to postulate its existence. It is now apparent that prolactin-inhibiting factor is the neurotransmitter **dopamine**.

(DSM)

Prolactin-releasing factor (PRF)

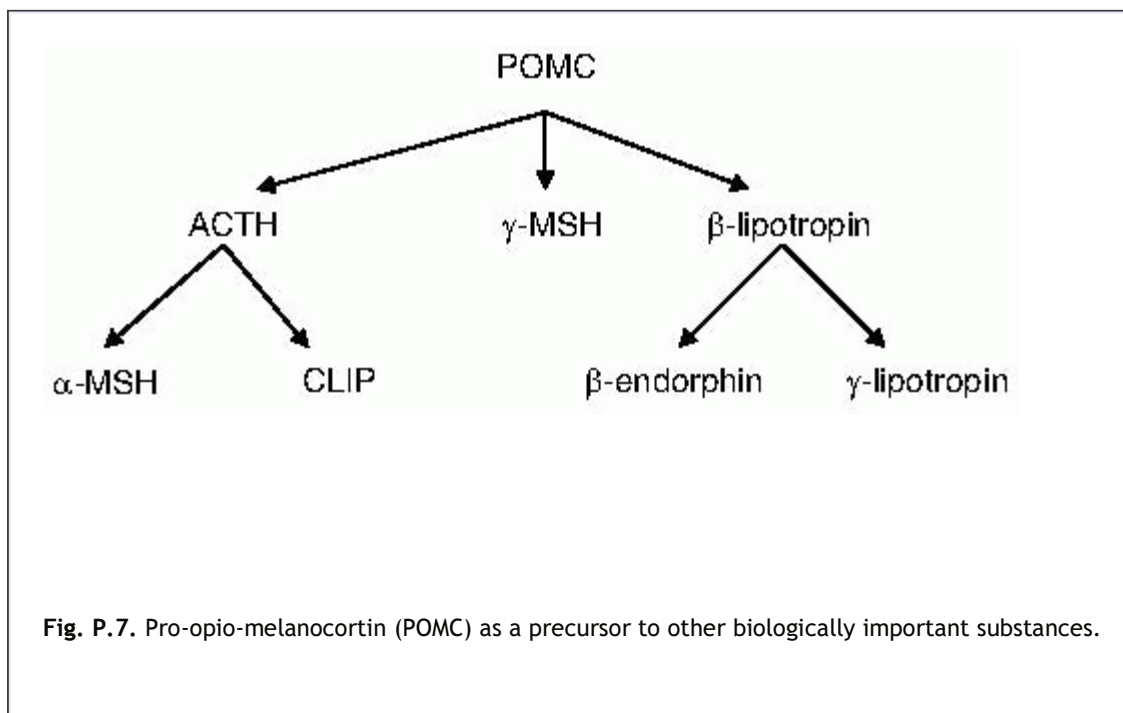

Also known as prolactin-releasing hormone (PRH, PRLH)/and prolactin-releasing peptide (PrRP). Although the regulation of prolactin release appears to be largely under inhibitory control, a number of stimulating factors exist, such as **oestrogen**, **gonadotropin-releasing hormone** and **thyrotropin-releasing hormone**. Prolactin-releasing factor is a specific peptide produced by the **hypothalamus** that is released in a pulsatile way and that stimulates the production of **prolactin** by the **pituitary gland**. This peptide is not hormone-specific and also appears to increase the release of both **corticotropin-releasing hormone** and gonadotropin-releasing hormone.

(DSM)

Pro-opio-melanocortin (POMC)

Pro-opio-melanocortin is an important biochemical precursor synthesized primarily by the anterior **pituitary gland**, **hypothalamus** and melanocytes in the skin; it has the potential to give rise to a number of biologically important substances (see Fig. P.7). Initial cleavage may be to adrenocorticotrophic hormone (**ACTH**, which leads to cortisol secretion), γ -melanocyte-stimulating hormone (γ -MSH, which stimulates melanin pigment production in melanocytes) and β -lipotropin (which is involved in fat and lipid metabolism). Depending on the cell type, ACTH may be further metabolized into α -melanocyte-stimulating hormone and corticotropin-like intermediate peptide (CLIP, or corticotropin-like intermediate lobe peptide, the normal function of which is unknown but which may be used as a biomarker in certain forms of cancer). β -lipotropin may also be further metabolized into β -**endorphin** and γ -lipotropin (which may itself be further metabolized to α -lipotropin).

(DSM)

Prostaglandin

Prostaglandins are a member of the eicosanoid family and are found in a wide range of species such as insects, fish, corals, birds and mammals. Prostaglandins are lipid compounds synthesized from essential fatty acids in any cell in the body, with the exception of red blood cells; prostaglandins do not travel in the blood like hormones but are used within the cell to regulate many different cellular mechanisms. Prostaglandins carry out a wide range of functions that are vital for

P.493

homeostasis of the individual, such as maintaining **blood pressure**, **parturition** and associated events such as muscle contraction and nest building. Prostaglandins are also vital in a variety of male sexual behaviours such as **libido**, mounting and ejaculation. Prostaglandins also help maintain skin integrity and sleep-wake cycles. Integrity of the **central nervous system** is partially dependent on prostaglandins, as they are a feature of processes such as myelination.

Prostaglandins can be synthesized by two pathways. The first pathway is initiated with double-unsaturated omega-6 linoleic acid (linoleic acid), while the second begins with triple-unsaturated omega-3 α -linoleic acid (α -linoleic acid). The linoleic acid pathway gives rise to series 1 and series 2 prostaglandins. Series 1 prostaglandins (TXA₁, PGE₁, PGF_{1 α} and PGD₁) are formed from the precursor dihomo- γ -linolenic acid and are involved in clotting, dilation and **inflammation**. Series 2 prostaglandins (TXA₂, PGE₂, PGF_{2 α} , PGD₂, PGH₂ and PGI₂) are produced from the precursor arachidonic acid and function in parturition, reducing blood pressure, temperature modulation and regulation of clotting. The α -linoleic pathway produces Series 3 prostaglandins (PGE₃, PGH₃, PGI₃ and TXA₃) from the precursor eicosapentaenoic acid, which is found in fish liver oils. Series 3 prostaglandins have a protective role in the body and it is suggested that they help reduce incidences of asthma, heart attacks and arthritis.

Sexual behaviour

Prostaglandin F_{2 α} has been used in the swine industry to improve the sexual performance of boars by increasing boar libido and increasing successful mounting behaviours. The mechanism of how prostaglandin optimizes male **sexual behaviour** in swine is not clear; however, it has been suggested that PGF_{2 α} results in the testes releasing higher levels of the **steroid hormones testosterone** and **oestradiol**. Data supporting this hypothesis come from a study where it was found that boars with higher blood concentrations of oestradiol required less time to mount and begin ejaculation in the presence of an artificial sow (Louis *et al.*, 1994). Sexually inexperienced boars given intramuscular PGF_{2 α} have higher success rates when trained to an artificial sow compared with boars given a placebo. Sexually experienced boars injected with prostaglandin also showed a marked improvement in successful semen collection.

Prostaglandin influences other sexual behaviours in boars besides libido and mounting behaviours. Boars given a low dosage of prostaglandin execute mild scratching behaviour around the face and neck using the hind legs. High doses of

prostaglandin result in more vigorous scratching behaviour around the facial area. There is no evidence that administration of prostaglandin affects semen quality; however, it does increase ejaculation duration. Beef heifers undergoing prostaglandin immunization do not display oestrous behaviours for an extended period of time, due to the formation of, and extended life of, the corpus luteum. Prostaglandin causes the corpus luteum to regress; however, after immunization, the corpus luteum does not regress and continues to produce progesterone. Other behaviours such as **lying**, standing and eating do not appear to be affected by this process. Female garter snakes receiving a large dose of prostaglandin have inhibited mating and a large decrease in sexual activity, while garter snakes given a small dose of prostaglandin take up to three times longer to mate even though there are no differences in other steroid hormones (Whittier and Crews, 1986).

Nesting behaviour

Nest building is a natural behaviour carried out by female members of many species prior to parturition as one of the processes of preparation for the arrival of the newborn. This powerful maternal instinct is controlled by both internal and external factors. In swine, internal factors encourage the seeking out and preparation of the nest site; the sow begins nosing, rooting and pawing the intended area for the nest. External factors affecting **nesting behaviour** include environmental temperature, the availability of substrates such as straw, earth, sawdust or other substrates deemed suitable and sensory feedback.

Before parturition can begin, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is required, its function being to degrade the corpus luteum. As the corpus luteum regresses, **oestrogen** and **progesterone** concentrations decrease, which are required for the maintenance of parturition. As these hormones decrease, **oxytocin** and **prolactin** levels increase, allowing parturition to take place. Prostaglandin $F_{2\alpha}$ can be used to induce parturition. Pregnant sows injected with $PGF_{2\alpha}$ display nestbuilding behaviour shortly after. At about 12 h after $PGF_{2\alpha}$ is administered to the sow, a second, more intense bout of nestbuilding behaviours is evident, if the substrates are available, and parturition takes place approximately 22-36 h after $PGF_{2\alpha}$ is given. Sows in a pen with straw or a similar pen without straw both displayed pawing and rooting behaviours when administered peripheral $PGF_{2\alpha}$; however, rooting behaviours were more intense with sows in pens with straw. Space requirement is also important for $PGF_{2\alpha}$ nest-building behaviours to be displayed. Dosage levels of $PGF_{2\alpha}$ affect the type of behaviour carried out within the range of nest-building behaviours. Low dosages of $PGF_{2\alpha}$ were highly correlated to gathering behaviours of nest-building substrates, while at high dosages of $PGF_{2\alpha}$ these showed a higher incidence of pawing behaviours in pregnant sows (Burne *et al.*, 2001).

These effects of $PGF_{2\alpha}$ are specific to post-pubertal females; post-pubescent boars increase sexual behaviours such as mounting, scratching and libido, and juvenile pigs show signs of **pain** and changes in activity.

Stress

Prostaglandin E_2 (PGE_2) - a metabolite of arachidonic acid - is involved in the regulation of impulsive behaviours. This mechanism is mediated through the EP1 receptor, which is encoded by the *Ptger1* gene. Studies in rodents found that the PGE receptors EP1 and EP3 are effective through the **hypothalamic-pituitary-adrenal (HPA) axis**. Mice that lack the EP1 receptor display abnormal behaviours such as abnormal social interaction, impulsive behaviours and **aggression** towards **conspecifics**. These mice also become highly sensitive to sound and are startled easily. The EP1 receptors have been found to be expressed presynaptically in the amygdala and the paraventricular nucleus of the **hypothalamus**.

In a study to determine the function of PGE_2 and its receptors, **stress** was defined as either stress caused by sickness or as a psychological sickness. During sickness stress,

P.494

there is an increase in **cytokines** in blood, this increasing the expression of two enzymes, cyclooxygenase (COX) and PGE synthase (PGES), required for the synthesis of PGE_2 in **brain** microvessels. During psychological stress PGE_2 is produced in pyramidal neurons that have COX. Sickness and psychological stress stimulate PGE_2 production in structures in the brain, and this binds to EP1 receptors in either the amygdala or the hypothalamus. This pathway reduces the frequency of impulsive behaviours during times of stress.

Pain

Prostaglandin E₂ is also a mediator for inflammation, fever and spinal nociceptive processing. Arachidonic acid is converted to prostaglandin H₂ by the enzymes COX-1 and COX-2. Prostaglandin H₂ is then catalysed to PGE₂ by PGES. COX-1 is coupled to cytosolic PGES (cPGES), and COX-2 is coupled to microsomal PGES-1 (mPGES-1). COX-1 has been suggested as being involved in both spontaneous pain and slow-developing, diffuse pain. It has been suggested that COX-2 and mPGES-1 are involved in the processes of pain, inflammation and fever. In rats, it was found that inhibiting COX-1 and COX-2 decreased **nociception**. In addition, down-regulation of cPGES and mPGES-1 has also decreased nociception.

General health

In the cardiovascular system, prostaglandins of the E series are vasodilators of the vascular bed, causing a decrease in blood pressure. Prostaglandin F₂ also reduces peripheral blood resistance, but without any effect on blood pressure. Thromboxane is a prostaglandin that is primarily produced in platelets, and it functions as a vasoconstrictor and it inhibits platelet aggregation. Another prostaglandin, prostacyclin, is also an inhibitor of platelet aggregation and inhibits cellular proliferation of vascular smooth muscle. Endothelial cells in the lung produce prostacyclin and, alongside PGE₂, functions in maintaining the lung in a dilated state, modulating vascular tone and as a bronchodilator. Prostacyclin has also been implicated in respiratory distress syndrome.

In the gastrointestinal tract, prostaglandins have three main functions: motility, cytoprotection and secretion. Prostaglandins E₂ and F₂ are involved in the contraction of the gastrointestinal longitudinal muscle; PGF₂ is involved in the contraction of the circular muscle; and PGE₂ relaxes the circular muscle. Prostaglandins of the E series promote secretion of mucus and bicarbonate and, acting with prostacyclin, increase mucosal blood flow, promoting cytoprotection. The prostaglandin E series reduce gastric acid secretion but promote the secretion of water and electrolytes into the jejunum.

In the cortex of the kidney, prostaglandins are produced in the cortical collecting tubes, glomeruli and the arterioles. Prostacyclin is the major prostaglandin in the kidney cortex and it uses its vasodilatation capabilities to regulate blood flow and control both the filtration rate of the glomerulus and renin secretion. In the kidney medulla PGE₂ is the main prostaglandin; it is synthesized in the loop of Henle, collecting ducts and interstitial cells. Prostaglandin E₂ increases renal blood flow and decreases sodium transport from the loop of Henle to the interstitial cells. It also decreases urea and sodium reabsorption from collecting ducts and, finally, acts as a vasopressin antagonist to decrease water permeability. In doing this PGE₂ controls water and salt secretion from the kidney.

In skin, PGD₂ is the major prostaglandin produced and plays an important role in the integrity of the skin. Prostaglandin D₂ has a number of functions, including reducing platelet aggregation, decreasing nitric oxide release, regulating body temperature, increasing bronchoconstriction and modulating **sleep** patterns. In mice, it was found that decreased levels of PGD₂ were implicated in an increase in scratching behaviour. During the scratching behaviour, the toenails of the mice disrupt the subcutaneous layer, thereby damaging the skin; this precedes the onset of spontaneous dermatitis.

Proximate factor

A proximate factor is an internal or external **stimulus** that produces a particular response in an animal. Proximate causation focuses on the immediate or short-term events that are responsible for a behavioural or physiological response. For example, a proximate causal explanation for **feeding** is **hunger** or lack of feeding for some time.

PSE meat

Pale, soft, exudative, or PSE, meat is a classification of meat that is characterized by pale colour, lack of firmness and fluid seepage. The meat is generally inferior in taste and texture, and there is nutrient loss in the fluid seepage. Such meat is rarely used as a raw product, but is occasionally used as a portion of processed meat products. This condition is a result of a rapid decrease in the pH, along with high temperatures in the muscle after **slaughter**, resulting in an increased rate of glycolysis and a build-up of lactic acid. These combined conditions cause a disruption in the protein structure of the muscle tissue due to variable sizes of the sarcomeres, a component of the muscle fibres.

P.495

Acute stressors prior to slaughter and the condition known as **porcine stress syndrome** (PSS) are considered to contribute to this condition. Genetics has also been attributed as having an effect on the occurrence of PSE meat, with selection for increased leanness and feed efficiency resulting in a marked increase in the incidence of PSE meat. It has been suggested that the swine industry selected pigs against the occurrence of PSE meat while maintaining the selection for optimum leanness and feed efficiency. Rapid chilling of the meat immediately after slaughter and alterations to the pre-slaughter environment, including during transport and lairage, to reduce stress have been suggested as reducing the occurrence of PSE meat. If transporters and workers in the slaughter plants are properly trained in handling procedures that minimize animal welfare problems immediately prior to slaughter, then the risk of PSE meat production is also reduced.

Pseudogenes

A pseudogene is a DNA sequence that is not functional, i.e. it does not code for a protein, and that has a functional counterpart in the same organism (Hartl and Jones, 2005). It is presumed that pseudogenes are mutated relics of gene duplications in the evolutionary history of organisms.

Psychogenic

An adjective, meaning of psychological origin. It is applied to conditions in which the usual organic cause cannot be established, but a likely psychological one exists. For example, in psychogenic paralysis, there is no identifiable physical cause, and thus the condition is assumed to be a reaction to psychological trauma (where evidence for trauma or **stress** exists).

Psychology

Psychology as a discipline cannot be defined in any clear or straightforward way. Individuals who call themselves psychologists may study phenomena as varied as mental illness, the learning abilities of cephalopods, the nature of dreams, the neuroanatomy that underlies **fear** or the biochemistry of **stress**. Thus it would appear that subject matter cannot be a defining characteristic of the field.

The kinds of questions that psychologists ask might be another way to define the discipline. These include such ill-defined problems as: (i) determining the characteristics of human and non-human animal nature; (ii) understanding how the mind and body are related; (iii) investigating the extent to which genes versus environment versus interactions between the two determine behaviour; and (iv) understanding exactly what humans and other animals have in common with one another, mentally and behaviourally. Finding the answers to even one question of such a scope is a tall order for any discipline - and psychology in one way or another endeavours to take on all of these, plus more. The vague parameters of such questions, their diversity and their seemingly endless iterations prevent one from using these elements as a means by which to characterize the discipline.

Nor does methodology or approach suffice to define psychology. Psychology is not so much characterized by a single approach or suite of approaches as it is by recurring argument regarding which approach is most appropriate for its variable subject matter. Is the nature of the mind a topic suitable to empirical analysis, or is a qualitative approach more appropriate? Can behaviour be best understood by applying a molecular approach, breaking it into its smallest constituent elements? Or are behavioural phenomena best evaluated by taking a more holistic, molar approach that focuses on purpose or function? Debates such as these about the ideal methodology continue in the psychology literature.

An examination of psychology's history can in part explain the divisiveness that seems to characterize the field. Psychology is the product of an uneasy marriage between philosophy and physiology - two disciplines that are fundamentally different in their preferred method of enquiry. The dialectic between these two historical influences has shaped much of psychology's development, as well as the paradigms currently dominating the field. In fact, a brief review of that history is perhaps the best way to try to describe the field to non-psychologists.

In most introductory textbooks, psychology is defined as the scientific study of **brain**, mind and behaviour. That study is undertaken from many different levels of analysis - from the molecular level of genomics and brain biochemistry to the more molar level of family and social systems. Considering this discipline's unlikely parentage, however, it should come as no surprise that the textbook definition is not without controversy. There are practitioners in psychology, for instance, who argue that the empirical method cannot adequately be applied to some of the kinds of questions addressed by the field. There are others who assert that the mind, for instance, is not a topic suitable to the science of psychology, because it is impossible to subject it to empirical analysis. Indeed, there may be no single aspect of the field on which all psychologists agree. But the diversity of opinion, approach and focus in the field is also part of its richness. After all, we humans would hardly be satisfied by an explanation of ourselves as individuals that was too tidy and concise.

Although one can trace its disciplinary roots, it is hard to say precisely when psychology as a field began. If indeed psychology is a field in which the relationship between mind and body is considered and evaluated, then perhaps the very first humans who ever pondered the nature of their nature were the first psychologists. In this way, psychology may well be one of the oldest academic disciplines.

The word 'psychology' derives from the Greek word *psykhe*, meaning 'spirit' or 'soul' and the Greek word *logia*, meaning 'study of.' The etymology of the word clearly reflects this oldest and perhaps most fundamental of questions posed by psychologists: what is the relationship, if any, between the mind and body? Many early investigations in the field can ultimately be described as efforts to answer this question (see: **Dualism**, **Cartesian**).

For some philosophers, the mind was simply not something that could be subject to empirical analysis. The mind of an individual is a private, idiosyncratic thing, to which only the owner has access (and in some cases, as theorists like Freud would argue, even that access is limited). Nevertheless, there were those who insisted that the mind was indeed a subject

P.496

suitable for scientific investigation, and their efforts to pioneer means by which to ask empirical questions about personal experience paved the way for the new discipline's development.

Among these persons was the German physician and physiologist Wilhelm Wundt. Wundt was perhaps the first person to call himself a psychologist. In 1879 at the University of Leipzig (where he was teaching as a Professor of Philosophy!), Wundt established what many consider to be the first laboratory entirely devoted to psychological investigation, and it is this moment that is generally regarded as the formal establishment of the field. It did not take long after Wundt's initial work for others attracted to the field to begin to critique his methods and to develop their own brand of psychology.

Wundt's preferred method for investigating the nature of the mind was **introspection**, a technique he applied primarily to the study of sensory experience. In the mid-19th century, it was widely believed that psychological phenomena (such as **consciousness** and sensory experience) were not suitable for empirical study, since they could not be directly measured or manipulated. Wundt disagreed. He had studied under the physiologist Hermann Helmholtz, who had shown that a number of elements of human **perception** were measurable, and that sensory experiences of many kinds could be tied directly to the nervous system. Wundt believed that, with appropriate training, he could develop human subjects who could accurately and objectively report on their own experiences, using a common vocabulary that made data obtained in this way replicable and testable. While today it is difficult to imagine a science based on subjective self-report, Wundt was nevertheless a powerful advocate for the necessity of an empirical approach to the developing field of psychology. Paradoxically, his own preferred method of introspection is today considered quite the opposite of scientific rigour.

Intellectuals attracted to the new field of psychology had to travel to Germany to learn about the discipline from its new master, Professor Wundt. Among these pilgrims were the British psychologist Edward Titchner and the American psychologist William James. Upon his return home to the UK, Titchner found no ready home for his new ideas about a science of the mind, and thus he moved to the USA to take up an appointment at Cornell University. There, Titchner extended the ideas he had learned about in Leipzig into an approach to psychology called *structuralism*. Much as contemporary physicists believe that there is a fundamental particle from which all other matter is derived, structuralist psychology assumes that it is possible to break conscious experience into its smallest underlying components. By understanding its fundamental structure, Titchner believed, one can truly come to understand the nature of mental experience.

In vehement opposition to this approach was William James. James asserted that the mind was much more than the sum of its elements. Much like the Heisenberg uncertainty principle's assertion about the limits of our abilities to study atomic particles, James argued that consciousness was not something that could be stopped at a given moment in time so that it could be subjected to analysis. In so doing, he noted, one is no longer observing the phenomenon in which one was originally interested.

The structuralist approach, in James' view, was a bit like someone trying to explain a house by describing each of its bricks and boards individually. To James, the more important aspect of these components was how they all worked together to form a house. By analogy, the functions served by the mind are the important thing, and not the elements that come together to generate those functions. This emphasis on the adaptive utility of different mental elements became known as a *functionalist* approach. The functionalists stressed the application of data gathered in the name of psychology to everyday, real-world problems. Contemporary functionalists today include evolutionary psychologists who focus on the phylogeny and adaptive value of a wide range of behaviours, as well as neuroscientists who answer the mind-body question with the argument that 'mind' is nothing more than a function of the brain. This latter emphasis on immediate or proximate function is characteristic of most of the kinds of questions contemporary psychologists attempt to answer.

Other opponents of the structuralist approach of Wundt and Titchner included the German psychologists Max Wertheimer and Wolfgang Köhler. Both the functionalists and these German thinkers rejected the elementism of the structuralist approach. While the American functionalists emphasized the *purpose* of mental and behavioural elements, however, Wertheimer and his colleagues focused upon what they considered to be the wrong-headedness of the elemental approach itself. To Wertheimer, the mind could not be reduced to elements without distorting its true nature. From his perspective, organisms do not experience the world in small, discrete pieces, but rather in whole, meaningful configurations. The assertion that the whole of an experience was more than the sum of its parts became known as a *gestaltist* principle, from the German word for 'configuration' or 'whole'. The gestaltists argued that psychology should take a more molar approach

to its subjects. For instance, the study of behaviour from a more molar approach would mean focusing on a suite of behavioural elements that together might comprise a single goal-directed, purposive act.

An example of this approach put into practice can be seen in the work of Wolfgang Köhler during the early 1900s. Visiting the Prussian Academy of Science's anthropoid research station in the Canary Islands, Köhler became marooned there by the unfortunate and coincident start of World War I. Köhler did not make idle use of his time, however. He spent the next few years investigating the nature of intelligence and learning in chimpanzees, summarizing his research in *The Mentality of Apes* (1917). In this volume, Köhler described the holistic nature of chimpanzee problem-solving; in many cases, it did not seem to him as though the animals solved a problem through combining elemental experiences or through trial and error, but rather through the more global application of **insight**.

The gestaltist and structuralist perspectives thriving in Europe emphasized the power of descriptive analysis, and also the value of studying behaviour and mental experience as it occurred naturally - that is, outside of the artificial environment of the laboratory. These values set the stage for the coming field of **ethology** - the study of animal behaviour as it occurs in the natural environment. The legacy of the structuralists and gestaltists can also be seen today in the works of phenomenologist psychologists such as John Compton and Elisabeth Ströker.

P.497

Yet another school of thought in psychology that developed largely out of a rejection of structuralism is the *behaviourist* school (**see: Behaviourism**). Behaviourist thinkers, such as the Americans John Watson and **B.F. Skinner** and the Russians Ivan Sechenov and **Ivan Pavlov**, argued that psychology could *not* be a science as long as it continued to include in its scope of investigations the study of consciousness and mental phenomena. The mind, it was argued, was inherently unsuitable to empirical analysis. Mental experience was personal and therefore inaccessible to the kind of public testability demanded by the empirical method. Behaviour, however, was a different thing entirely. Behaviour could be observed by others and quantified; the conditions under which it occurred could be replicated and the causes of behaviour empirically tested. To the behaviourists, the only valid subject of study in a psychology that wished to call itself a science was behaviour (**see: Experimental analysis of behaviour**).

Focusing upon behaviour, the physiologist Ivan Pavlov documented the kinds of 'automatic' external triggers that invariably invoked the same response. He called these triggers 'unconditioned stimuli', and described the means by which other, previously neutral, stimuli ('conditioned stimuli') could come to elicit the same responses. The form of learning in which an organism appears to use the presence of one **stimulus** as a **signal** for another has come to be called *classical conditioning*, and it was Pavlov who first described this form of learning in detail. Principles of classical conditioning are employed today in many arenas of applied animal behaviour - from conditioning wolves and coyotes to avoid sheep to using milk barn stimuli to trigger milk letdown in dairy cattle (**see: Conditioning - types of**).

In America, psychologists such as Watson directed their attention to experience with the consequences of behaviour that could modify the frequency of that behaviour in the future. Operant conditioning (so called because the organism must operate on its environment in order for learning to occur) was the name given to this kind of learning in which animals learn about the consequences of their actions. Two primary kinds of consequence were described by the behaviourists: **reinforcement** (any consequence that results in a behaviour being more likely to recur) and **punishment** (any consequence that decreases the likelihood that a behaviour will occur again). The principles of reinforcement and punishment objectively described and empirically tested by early behaviourists are employed today in nearly every aspect of domestic animal handling.

Investigations by behaviourist psychologists into the proximate causes of behaviour also resulted in a compilation of rules or 'laws' for explaining behaviour, such as the assertion that all behaviour is the consequence of some environmental trigger or stimulation, and that no behaviour changes unless it is reinforced or punished in some way. Influenced by the Darwinian revolution in science that was taking place at the turn of the 19th century, behaviourists argued that all organisms learned in the same way, and that rules governing the shaping of behaviour applied equally to all living things - from amoebae to humans. Thus, if one wanted to understand learning in wild elephants, one could study learning in domestic rats maintained in a university laboratory, and any information gleaned from the rat studies was believed to apply equally to wild elephants.

The assumption of universal laws of learning that applied to all organisms, and the reliance on laboratory work rather than on observations of animals in nature, were among the elements of behaviourism attacked by ethologists such as **Konrad Lorenz**. Influenced by the same European schools of thought that had shaped gestaltist psychology, the ethologists argued that behaviour could not be understood separate from the environment in which it evolved: natural history and behaviour had to be taken as one. Necessarily, then, little if anything useful could be learned about behaviour from examining it

under laboratory conditions. The feud between classical ethologists and classical behaviourists was to influence the development of **comparative psychology** for years to come.

Comparative psychology focuses on the comparative study of human and non-human animal behaviour - traditionally in laboratory or other controlled settings. Perhaps the first comparative psychologist (though not by training) was **Charles Darwin's** disciple, **George J. Romanes**. Romanes considered that, if all living things were descendants of a common ancestor, then at least some components of intellect and behaviour should be similar across species. To support his point he collected anecdotes of non-human animals engaging in behaviour that suggested problem-solving and reasoning capacities much like those of humans. Though Romanes' underlying assumptions seem reasonable, his casual methods and anthropomorphic interpretations were the subject of an aggressive attack by the American psychologist C. Lloyd Morgan. Morgan's argument that parsimony should be the rule applied in interpretation of behavioural data, and that data should be based on empirical observation, became known as **Morgan's Canon**, and this principle dominates the field of comparative psychology today.

Still other schools of thought that can be found under the umbrella of psychology include the philosophy of Sigmund Freud and his followers - a philosophy that emphasized the influence of unconscious motivations in the shaping of behaviour. Additional perspectives include those of Kurt Lewin (who emphasized how social situations affect behaviour) and George A. Miller (who is credited with launching the cognitive revolution in psychology). Each of these perspectives (like the others reviewed above) endorses a different preferred theoretical explanation for behaviour, and often a different preferred methodology for pursuing hypotheses derived from those explanations.

In summary, psychology as a field is nearly impossible to define - it cannot be reliably identified by its subject matter, by its methods, nor by its preferred levels of analysis. Nevertheless, the study of brain, mind and behaviour reaches across a great many areas of interest to students of applied animal behaviour, and thus it behoves us to try to understand the complexity of this many-faceted discipline.

Punishment - types of

If the consequence of an action reduces the likelihood of the action being repeated, this consequence is said to have punished the action. In other words, punishment is anything that reduces the likelihood of the preceding action being repeated in a similar situation.

Punishment can occur in one of two ways, either through the presentation of something **aversive**, in which case it is referred to as positive punishment, or through the removal or denial of something pleasant, which is then referred to as negative punishment, or 'response cost'. For example, an electric shock applied to a rat when it presses a lever is an example of positive punishment, if lever-pressing behaviour then reduces in the long term. On the other hand, putting a dog on a lead (removal of freedom) to reduce overexuberant off-lead behaviour would be considered a negative punisher if the boisterous off-lead behaviour is then reduced in future.

The consequence can only be considered punishing if it has a suppressing action on the behaviour at which it is aimed. Aversive consequences without long-term effect on the preceding action are not punishment, although they may disrupt the behaviour in the short term. If the aim was to punish the behaviour, this inappropriate use of an aversive stimulus raises

ethical concerns over the management of the animal. Disruptive stimuli (interrupters) may be used in training to distract the animal (giving the trainer time to redirect the animal or take control of the situation in some way) - for example, clapping one's hands to startle a dog that is barking so that the dog can be directed towards expressing a more acceptable behaviour. However, what may serve as a disruptive stimulus for one individual may be a punisher for another, more sensitive, individual.

The effect of punishment is assessed by its long-term impact and not by its immediate effect on the behaviour, since a goal-directed behaviour (**appetitive behaviour**) that is followed by a variant of its goal will cease in the short term. Thus an attention-seeking behaviour that is followed by some form of **attention** (such as being reprimanded) may not actually be punished by this consequence, even though behaviour stops in the short term. To the contrary, it may actually be reinforced by the giving of attention, and so more likely to occur the next time the animal seeks attention.

The fact that whether or not an event constitutes punishment is dependent on the subject is important to bear in mind at all times when interacting with animals, as it allows us to determine whether actions the trainer considers not to be aversive are perceived as such by the animal. If a behaviour is reducing in frequency (being suppressed), one of the possible explanations may be that something is punishing the behaviour and thus something the trainer considers innocuous is perceived as aversive by the animal. There are also examples of where the event punishing the action may not be a deliberately administered stimulus or even a direct consequence of the animal's behaviour. Something that occurs as a random event but coincides with the action of the animal and is perceived as aversive by the animal may punish the prior behaviour. For example, if a cat is using the litter tray as a boisterous dog runs into the room, litter tray use may be punished and a **housesoiling** problem begin.

Just as conditioned reinforcers are used in training (**see: Reinforcement**), conditioned punishers can also be created and utilized. If a neutral stimulus is paired sufficiently frequently with an aversive event (be it negative punishment or positive punishment), this stimulus will take on the quality of a punisher and can then influence behaviour. Conditioned punishers can be very useful, especially with regard to the timing of delivery of punishment in practice (see later); however, it is important to realize that the potential negative consequences of the primary punisher will also be seen with the use of conditioned punishers. It is also important to realize that conditioned punishers can be created inadvertently. It has been demonstrated that the environment and people present at the time of punishment delivery can also take on punishing characteristics (Schilder and van der Borg, 2004), which has potentially serious implications for the relationship between trainer and animal, as well as between the subject and other animals present at the time punishment occurs.

In addition, from a declarative knowledge perspective (i.e. the information an individual has), the use of punishment does not increase certainty about the environment and so it is not conducive to good **welfare**. This is because punishment informs the individual that a given action was not appropriate, but does not, on its own, provide information about what would be appropriate in such circumstances.

Therefore, significant reliance upon punishment as a means of training an animal or teaching people is highly controversial. If it is to be used it is important that it is used correctly to ensure its success, as well as to safeguard the welfare of the trainee. The following must be considered when utilizing punishment in training.

The contiguity of punishment and behaviour to be punished is important for the punisher to be effective. Timing of punisher delivery is critical, as an association needs to be made by the animal between the action and the consequence and, if there is time for an additional action to intervene between the undesirable behaviour and the aversive event, then the latter behaviour may be the one associated with punishment rather than the target behaviour. A delay between action and punishment delivery is less effective in suppressing behaviour in the longer term.

Secondly, the intensity of the punisher needs to be sufficiently aversive to suppress the undesirable behaviour, but not so aversive that it causes substantial emotional interference. **Fear** and **anxiety** are not only undesirable from a welfare perspective, but they may also interfere with the learning that is trying to be achieved; for example, the animal may become more inhibited and therefore less likely to exhibit the desired behaviour. Aversive stimuli of insufficient intensity are not only ineffective, but may result in **habituation** if frequently repeated, which may mean that a more intense event will need to be applied to achieve the desired effect. Should the intensity be gradually increased over time, the intensity may be escalated to a point where serious welfare concerns are manifest without the desired effect being achieved. Thus the appropriate application of punishment requires considerable skill, as it will often vary for a given behaviour and between different individuals.

The behavioural consequences of punishment are often situation dependent and thus, for it to generalize across

contexts, repetitions in different contexts will normally be necessary. Single-trial learning can occur when event intensity is sufficiently great. However, if this is not the case, then punishment needs to be delivered at every occurrence of the undesirable behaviour, or else negative reinforcement of the behaviour in the circumstances that avoid punishment may occur.

Another important consideration associated with the potential use of punishment relates to its impact on motivation towards a goal rather than on the behaviour. The motivation for the goal is not removed by suppressing the initial behaviour associated with it, and thus the animal may start to perform a new behaviour in place of the old behaviour directed towards achieving the same goal. This behaviour too may be inappropriate. Thus, whenever a punishment is utilized as a means of reducing behaviour, a new appropriate behaviour needs to be reinforced to guide the animal towards appropriate behaviour.

Q

Qualia

Qualia (singular: quale) are the subjective **feelings** accompanying sensory experiences, sometimes referred to as ‘raw feels’. Classic examples include what it feels like to see red, smell roses, taste coffee or experience **pain**. The term was first coined by Lewis (1929), and it is a key concept in phenomenal consciousness.

Qualitative measure

A measure of something that has a discrete meaning or quality that cannot necessarily be described in terms of quantities (i.e. numerically). For example, eye colour can be described in terms of categories of colours: blue, brown, green, etc. Qualitative measures of animal behaviour might be whether an individual is performing one of the following categories: running, walking or standing.

(KT)

See also: Measuring behaviour; Quantitative measure

Quality of life

In discussions focusing on human treatment of animals, the term ‘quality of life’ is sometimes used as a synonym for ‘**welfare**’ to refer to animals’ **well-being**. The term may serve to remind the reader that the study of animal welfare is analogous to the study of human quality of life.

Quantitative measure

A quantitative measure describes something in terms of quantities (i.e. numerically) - for example, the number or weight of individuals. Quantitative measures of animal behaviour might include the volume of a **vocalization** in decibels or the length of time for which an individual is vocalizing. Quantitative measures may be either objective or subjective.

R

Rabbit

The family Leporidae of the order Lagomorpha comprises 11 genera, which are commonly known as rabbits and hares. As a highly adaptable species, rabbits are found throughout the world, with individual species having their own origin. The European rabbit (*Oryctolagus cuniculus*), native to south-west Europe and north-west Africa, is the only species of this genera to be domesticated and has become a popular laboratory, farm and **companion animal** both within and outside its native range.

At the beginning of the 19th century, selection of rabbits for colour, shape and size began. As farm animals, Californian and New Zealand rabbit breeds are most commonly used for meat, due to their ability to grow quickly. Angora rabbits, with their long, silky coats, are most commonly used for fur production, and New Zealand rabbits are usually used for laboratory purposes, mainly medical and safety product research. The most recent domestic role for rabbits is within the companion animal sector, where over 2.8 million rabbits are kept in 0.7 million households as pets and/or exhibition animals (conformation or show jumping) in the UK alone. In some countries rabbits are considered a significant pest species, especially where they are not native (**see: Exotic species invasion**).

There are many differences in the conformation of modern domesticated rabbits and European wild rabbits. The wild European rabbit is small and grey-brown in colour, growing up to 45 cm in length and weighing an average of 1.3-2.2 kg. There are over 50 breeds and 500 varieties of domestic rabbit recognized, with a large range in size and weight. The largest of these breeds, the Continental Giant, is a minimum of 65 cm in length and 5.5 kg in weight, while the smallest breed, the Netherland Dwarf, weighs a maximum of about 1.2 kg. In addition to the variety of sizes, domestic rabbits also come in lop breeds, meaning that the usually upright, alert ears (see Fig. R.1) are drooped by the sides of the head (see Fig. R.2).

In fully lopped rabbits, the ears are incapable of upright movement. Similar to other domestic species, the breeding of extreme phenotypes can be a concern. Some of the giant breeds may grow too quickly or be too heavy for their skeletal structures, some smaller breeds have blunted noses that may change the rabbit's field of vision or interfere with dental function, and rabbits with lop ears are more prone to ear infections as humidity within the ear changes.

Rabbits are herbivorous, with diets that are naturally very high in fibre. In the wild the diet would be made up of a variety of grasses and hays. However, this type of diet is comprised of large amounts of relatively indigestible cellulose. A unique normal feeding process involving **coprophagy**, or re-ingestion of faeces, allows nutrients to be obtained from food during a second passage through the digestive tract. Thus rabbits have two types of faeces: soft, mucus-covered faeces that the rabbit eats directly from its anus; and the commonly seen hard, dry faeces that are the waste left over from the second passage through the digestive tract. Domesticated rabbits have similar digestive processes to their wild ancestors;

P.504

however, they often get a very different diet. This diet usually includes supplementation or even replacement of this natural diet with dry/pelleted food. Many of these commercially available feeds are often high in carbohydrate (particularly sugar) and protein but low in fibre, a combination of which often results in health problems. The diet of the rabbit can affect their behaviour; for example, overweight rabbits may no longer engage in coprophagy or the behaviour may become diminished. In the wild, rabbits spend a large part of their active time finding and eating suitable grasses and hays. Pelleted feed provided readily in bowls for domesticated rabbits is consumed more quickly than a high-fibre diet and does not require any effort to find, leaving the rabbit with more free time and perhaps an unfulfilled **need** to forage.

Fig. R.1. Erect-eared rabbit.

Fig. R.2. Lop-eared rabbit.

European rabbits (unlike many other species of rabbit) are gregarious in the wild, living in groups of up to 20 individuals in underground tunnels known as warrens that cover vast amounts of space. In general, when domestic rabbits are housed in large group enclosures, the behavioural repertoire of their wild counterparts is retained. However, this housing system is rarely found within modern-day society, with rabbits mainly being kept in singles, pairs or small groups, and different behaviour or revision of behaviour is often seen. In addition, rabbits in the wild are **crepuscular**, that is, they are most active at dawn and dusk, while domestic rabbits tend to have their active periods at times that fit with their human caregiver's schedule. For example, a pet rabbit may get turned out in the garden during the afternoon for a run or may be fed mid-morning. It is not yet known what effects, if any, this may have on domestic rabbit **welfare**.

In many countries, there is a dichotomy in the statutory and legal protection provided for rabbits kept for commercial versus companion purposes. Laboratory and farm rabbits are typically housed in cages or pens, individually or in groups. In the UK, housing guidelines and **codes of practice** have been produced by the Home Office, Department for Environmental Food and Rural Affairs (Defra) and the Laboratory Animal Breeders Association (LABA), to provide basic welfare requirements, but there is less protection for companion rabbits within the UK, where housing is usually either outdoors in hutches or indoors as house rabbits. The **RSPCA** and Rabbit Welfare Fund (RWF) provide housing recommendations based on the **five freedoms**, although there are no specific minimum housing requirements. Codes are being developed in light of recent UK legislation that should afford pet animals the same protection as farmed ones. There is a general consensus that rabbit housing, regardless of the purpose of the rabbits, should be large enough to allow hopping and sitting with ears alert, that there should also be an area with a minimum height of 45 cm and that a shelter be provided.

As with many domestic species, rabbits kept in conditions very different from their wild counterparts are prone to development of **abnormal behaviour**, including stereotypic behaviour patterns. These are especially prevalent in laboratory, fur- and meat-farming conditions, where the welfare of the rabbits has to be balanced with cost of the end product. The most commonly found abnormal behaviour patterns in rabbits are circling, fur pulling/plucking and water bottle 'playing' or **polydipsia**.

Raceway

Otherwise known as a chute, a raceway is used to move animals in a controlled manner from one place to another, usually single file. Sometimes raceways are used to administer drugs to animals, as when tightly packed they are unable to move. Attempts to encourage animals to move down a raceway may be made by people shouting at, hitting or goading them with sticks or electronic sticks (**goads** or prodders). Using excessive pressure to force animals to move in a raceway will lead to them becoming frightened, difficult to handle, unwilling to enter the raceway a second time and, on occasions, dangerous. Animals usually prefer to move from a dark area to light. Solid walls and curved raceways are best, but moveable gates are an acceptable alternative. V-shaped races support the animal and prevent them from lying down. If they do lie down, animals may be reluctant to get up.

Raceways may lead into a loading ramp and then into a vehicle, in which case the loading ramp should have side-gates and a slope of suitable incline for the type of animal being moved (e.g. less than 4-in-7 for cattle and a step-up of less than 20 cm). Sloped raceways or ramps should have battens for the animals to get a grip, and the floor should be non-slip. Adequate staffing is essential for moving cattle through raceways and the animals should be moved slowly and preferably without the use of goads. Staff should be calm, confident and able to predict the animals' behaviour. Sticks can provide a useful means of extending the arm to accelerate movement, but should not be used to hit the animals with unnecessary force, using persuasion rather than aggression. Raceways may also lead into a crush, where individual animals are managed, often for veterinary procedures, weighing or pregnancy diagnosis. The ideal crush has solid sides to make the animal feel secure, but frequently this is not possible as access is needed, for example to hooves when the animals are treated for **lameness**.

Animals are put into a raceway either for one-by-one treatment such as drenching, or to move them in single file into an area where they can be handled individually, as in a crush or dip. Although they move more easily in the race if it has solid sides, they will accustom to one with open sides, which should preferably be V-shaped to support the animal and prevent it from lying down. Cattle prefer to move in a circular rather than a straight direction and, if they are stressed, bunching may occur. Often an animal may then lie down, and it may be difficult to make it stand again.

Rat

Laboratory rats (*Rattus norvegicus*) in the zoological order of Rodentia (**rodents**) are descended from the wild rat. Albino rats, caught on the trading ships, were used for showing and research (most notably at the Wistar Research Institute in the USA). Hooded rats, so called because of the dark fur over the back of the neck, were probably assigned to the sport of rat catching by dogs. The long and close association of rats with humans probably facilitated taming them, as well as causing **disease** transmission.

Ratites

Ratite birds are cursorial, flightless birds typically of very large size. Their primitive palate defines them as part of the Palaeognathae (along with the Galliformes and Anseriformes) but, although being closely related, the various species are recognized as a distinct taxonomic grouping. Living ratites include the **ostrich** (Struthionidae) of Africa, the emu (Dromaiidae) and cassowaries (Casuariidae) of Australasia, and the rheas (Rheidae) of South America. Extinct families included the elephant birds (Aepyornithidae) of Madagascar and the moas (Dinornithidae) of New Zealand. Although the kiwis (Apterygidae) of New Zealand are very much smaller they are also classed as ratites, and share a close taxonomic relationship with the moas. Penguins (Spheniscidae) are of the Neognathae and so are not ratites.

All ratite birds lack well-developed wings and so are well adapted to rely on their legs for locomotion. They lack the flight **feathers** with interlocking barbs seen in other birds and are covered by long, soft feathers that are more reminiscent of down feathers seen on other birds. With the exception of the kiwis, ratites are **diurnal** and have herbivorous diets of foliage or, in the case of the cassowaries, fruit. They lay the largest of all bird eggs (400-1500 g), which hatch into **precocial** offspring.

Ratites have gained prominence in recent years due to their commercial exploitation. Farming of the ostrich for feathers was started in the mid-1860s in South Africa, and soon spread to other parts of the world including Europe, North America and Australia. Around the same time rheas were exploited for their feathers. However, due to the collapse of the feather market after World War I, farming of ostriches went into severe decline, surviving only in South Africa. After World War II, ostrich farming revived in South Africa with the development of a leather market, and then a market for leg meat. During the 1980s economic sanctions against South Africa curtailed the supply of ostrich hides to the world market. The gap in the market was recognized in the USA, where interest in farming ostriches increased rapidly, largely fed by unrealistic prices for birds and aggressive marketing. Against this backdrop, interest spread rapidly around the world, but it soon became clear that the prices were unsustainable and that maintaining ostriches in many countries of the world was very difficult and unprofitable. Interest in ostrich farming outside of South Africa had all but disappeared by 2000.

Farming of emus had been practised in Australia since the early 1970s, but there was considerable interest in emu farming in the USA, largely because the birds were smaller and easier to manage. For the same reason rhea farming was also promoted in the USA and adopted around the world. However, unlike the situation for the ostrich, markets for leather, meat and feathers from these species did not exist and so farming enterprises have been slow to develop and interest typically waned around the world. In its native Argentina the rhea is being investigated as a species that could be used commercially to exploit the environmentally sensitive grassland that is so easily destroyed by cattle.

Ratite farming led to considerable welfare issues because of the inexperience of many of the people attempting to keep the birds. Poor husbandry and a lack of understanding of the basic needs of ratites in captivity led to problems of high mortality, poor growth rates and chronic health problems in many birds. In particular, farming of ostriches and emus at northern latitudes promoted grave concern over the ability of birds to survive colder temperatures and wetter conditions. Despite such concerns, research into the **welfare** of ostriches, emus or rheas was not funded by producers or other agencies and so reliable reports of either good or bad practice, or how the birds respond to novel environments, are rare. Even in

South Africa, studies into the welfare of ostriches appear to be a low priority. Although the popularity of ratite farming has declined on a global scale it remains locally of interest, in several countries around the world where environmental conditions are favourable. How welfare issues are being addressed in these locations is largely unknown at a scientific level.

(DCD)

Rats and mice

The terms ‘rats’ and ‘mice’ can refer to many different species, most of which are in the family Muridae, but the species with the closest relationships with humans and which have been extensively domesticated are the Norway or Brown **rat** (*Rattus norvegicus*) and the house **mouse** (*Mus musculus*). Because of their relationships with humans, these two species have the most diverse and complex man-made welfare issues of all rat and mouse species, so this article focuses on them.

Rats and mice are **rodents**, an order that makes up about 40% of all mammal species, and that includes squirrels, **hamsters**, gerbils, **guinea pigs**, voles, mice and rats, among many other species. Rodents are characterized mainly by their teeth, which are specialized for gnawing through hard substrates; these grow continually throughout the rodent’s lifetime and, as the rodent gnaws, the teeth are worn down, retaining their sharpness. In **captivity**, **welfare** problems can result if gnawing substrates are not provided, because the teeth can overgrow, causing difficulties with chewing food, and causing physical injuries to the animal. Rat and mouse teeth are also one characteristic that has led to them becoming major pest species. Rats and mice have three main relationships with humans, and their welfare issues differ depending on these contexts: they exist as pest species, as **laboratory animals**

P.506

and as **companion animals**. Each of these contexts is discussed in turn, after a description of their characteristics as wild, undomesticated animals.

Wild rats and mice

R. norvegicus and *M. musculus* are generalist species, living in diverse habitats across all continents except Antarctica. They are opportunistic omnivores, consuming a highly varied and flexible diet, and they are highly social animals, with social structures that can vary depending on the resource availability of the habitat they occupy (Berdoy and Drickamer, 2007). Their general biological characteristics in the wild are shown in Table R.1. Despite generations in captivity, even domesticated rats and mice retain many of the characteristics of their wild ancestors, so the information on their wild biology can explain some of the welfare issues they face in captivity.

Sensory perception and physical abilities

Rats and mice usually show **nocturnal** or **crepuscular activity**, being most active at dawn and dusk, but their **circadian rhythms** are flexible to some extent, responding to food availability, weather conditions and **predation** risk. Because they usually occupy dimly lit environments, their eyes are extremely sensitive to small differences in light intensity (Burn, 2008). They can see colours, having two cone types peaking in the green and ultraviolet wavelengths, but their acuity is very poor, so their vision would appear very blurred to a human.

Their hearing overlaps with humans’ but also extends into the ultrasound (humans hear from 0.02 to 20 kHz; rats hear from 0.25 to 80 kHz (Burn, 2008); and mice hear from 10 to >100 kHz (Latham and Mason, 2004)). Correspondingly, they vocalize audibly using a variety of ‘squeaks’, and also ultrasonically. Their ultrasonic **vocalizations** include: (i) a male courtship ‘song’ in mice and rats; (ii) long calls that occur in negative situations and after male ejaculation; and (iii) a highly variable ‘laugh’ that mainly occurs in positive situations. Rats and mice have extremely well-developed olfactory senses, including a well-developed **vomeronasal organ** specialized primarily for detecting non-volatile **pheromones**. Olfactory cues allow them to discern each others’ characteristics including sex, kinship, health, reproductive state, familiarity and **dominance** status. Both species produce an alarm **odour** in negative situations, and rats also produce a reward odour that attracts colony members to **resource**-rich areas.

Table R.1. Some general biological characteristics of rats and mice in the wild (mostly taken from Berdoy and Drickamer, 2007; Wurbel *et al.*, 2009).

Biological characteristic	Rat (<i>Rattus norvegicus</i>)	Mouse (<i>Mus musculus</i>)
Adult female body weight (g)	250-300	15-21
Adult male body weight (g)	250-500	17-23
Age at weaning (days)	16-34	21-30
Age at puberty (weeks)	9-15	6-11
Gestation duration (days) 20-23	19-21	
Oestrus frequency if not mated (days)	4-5	4-5
Litters per year (per female)	4-6	Limited data
Pups born per litter (n)	7-8	5-9
Pups weaned per year (n)	20-30	Up to about 50
Home-range size (m ²)	30-45 or more rarely up to about 150	2-5 but can be orders of magnitude higher if nomadic
Life expectancy (weeks)	Limited data	11-15
Maximum lifespan (months)	12-18	12-18

Being generalist omnivores, rats and mice have similar gustatory senses to humans, tasting sweetness, saltiness, sourness, bitterness and umami (the ‘fifth taste’). Like us, they tend to favour foods high in sugar and fat, and to avoid bitter foods, many of which contain natural poisons (**see: Diet selection**). Rats and mice have highly sensitive whiskers (vibrissae) capable of making fine tactile discriminations. They are also thigmotaxic, meaning that they usually choose to maintain physical contact with vertical surfaces, so they tend to move alongside walls or other landmarks, rather than across open spaces.

Both rats and mice are adept at climbing (although not compared with some other closely related species such as the black rat, *Rattus rattus*), and also at digging. They dig burrows, with tunnels that connect chambers for storing food or for sleeping in. Both species build nests inside the sleeping chambers, especially when raising young, but mice build more elaborate cup-shaped nests than do rats; rats often just **sleep** on flat pads of material. The nesting materials depend on what is locally available and can include dry leaves, grass, feathers or paper. Rats also have a propensity for swimming, capable of swimming up to about 400 m across open water (Russell *et al.*, 2005), but mice usually avoid immersion in water.

Foraging

Both species are central-place foragers, so they tend to forage around the burrow site and, when they find food, they carry it back to the burrow or to the nearest harbourage site to consume it. Rats and mice eat seeds, fruit, nuts, molluscs, eggs, small vertebrates and any food made available by humans (Berdoy and Drickamer, 2007; Wurbel *et al.*, 2009). Rats have also been known to dive for molluscs or for eels caught in fishing nets. They are more predatory than mice, and can kill small mammals, birds or reptiles, sometimes leading to conservation issues when they colonize islands and prey on endemic species (see: **Exotic species invasion**).

P.507

The diversity of rat and mouse diets enables them to spread into diverse habitats, but it comes at a cost, because every unfamiliar substance eaten could contain toxins or pathogens. Both species therefore initially sample very small quantities of unfamiliar food, and learn to avoid it if they become unwell afterwards. They also learn socially (see: **Social learning**) what each other have eaten through olfactory cues (Burn, 2008); for example, as well as being attracted to conspecifics' feeding sites through reward odours, carbon disulfide present in rats' breath causes conspecifics to prefer foods that they smell on each other. They also avoid new foods they have sampled if they subsequently smell an ill conspecific, known as the 'poisoned partner effect'. Rats have two additional mechanisms that protect them from poisoning: (i) they can be highly neophobic (avoiding novelty), depending on genetic and environmental factors; (ii) and they have very high diversity in the genes regulating enzymes for denaturing toxins (Berdoy and Drickamer, 2007).

Population structure and social and reproductive behaviour

In large resource-rich areas, rats and mice live in large dynamic colonies with polygynandrous or promiscuous mating systems, respectively (Berdoy and Drickamer, 2007; Wurbel *et al.*, 2009). However, when resources are more scarce or widely distributed, they exist in small polygynous groups, where one dominant male usually cohabits with one or more females and their offspring. Dominance and territorial boundaries are marked using **urine**, mainly deposited by the dominant male, which will be overmarked by challenging males and refreshed by the dominant male, who patrols the territory many times daily. In mice, urine marking can lead to visible pillars of dried proteins from the urine deposits. **Aggression** is more common in males than females, but is rarely or never directed towards pre-pubertal individuals.

The dominance structures differ between the two species: in mice, males frequently fight for dominance and the larger mouse usually wins, but in rats the hierarchy is more stable. This means that rats fight more rarely, and the hierarchy is predicted more by age than by size in stable environments (rats and mice grow continually throughout their lifetime). The lower incidence of fighting in rats also goes hand-in-hand with their more diverse repertoire of postural **signals**, meaning that overt fights are usually unnecessary. In fact, rats have the most diverse forms of **play** of all rodent species studied to date, and even play as adults (Pellis and Iwaniuk, 2004). In both species adolescent, subordinate males are the first to disperse from the natal territory if resources (including mating opportunities) become scarce, but in mice females are almost as likely to disperse as are males. However, dispersing individuals have a very low chance of survival.

Mice and rats exercise mate choice, with pairs that choose each other having fitter offspring than pairs that have had no opportunity to select their mate (Berdoy and Drickamer, 2007). Courtship involves the females giving olfactory and postural signals (hopping, darting and ear wiggling) that they are ready to mate, and males in larger colonies competitively chasing the females. The females will often nest cooperatively, helping to raise each other's young. In small colonies where there is a dominant male, the dominant male may kill any offspring not fathered by him, but in larger colonies this is rare, perhaps because it is difficult for the males to discern the paternity of litters. Litters with multiple paternity are fairly common, at least in mice. Also, pregnant female rats deposit a pheromone in the nest that discourages cohabiting males from killing the females' offspring (Burn, 2008). Females of both species can reproduce all year round but, in reality, they only breed when resources are fairly plentiful and the temperature is warm enough, so this usually limits breeding to the spring and summer.

Mortality

In the wild, fewer than 50% of rats and mice survive beyond puberty, and still fewer survive to reproduce. Deaths are often from lack of resources, fighting injuries or disease, but can also be due to predation. Their main predators are carnivores, such as foxes, cats and mustelids (e.g. mink, weasels or polecats), and birds of prey. Their circadian rhythm is one mechanism of **predator avoidance**, with their nocturnality making them cryptic from visual hunters but, when nocturnal hunters are prevalent, rats become diurnal (Berdoy and Drickamer, 2007). Rats and mice, even after generations of

domestication, are also innately fearful of fox, cat and mustelid odours. Another major cause of death for commensal rats and mice (those sharing resources with humans) is, of course, pest control by humans.

Rats and mice as pests

Rats and mice cause billions of dollars of damage annually, consuming stored food, chewing through electrical cables and they can carry diseases. Rats are blamed for carrying more diseases than mice, and several studies have found that rats do harbour many pathogens and parasites that can harm humans (Berdoy and Drickamer, 2007) - **zoonotic disease**. However, it was *R. rattus*, not *R. norvegicus*, that carried the flea that caused the bubonic plague, and the few studies that have investigated mice as disease vectors have shown that they too can carry diseases, such as salmonella. Phobias of mice, and particularly of rats, are fairly common, and the media's portrayal of rats is especially negative, with them often being used to convey scenes of squalor or horror.

Perhaps for these reasons, the welfare of rats and mice in pest control is of low priority on the public agenda. However, some of the methods used to kill the many millions of rats and mice would be considered inhumane in other circumstances (**see: Pest control - ethics of; Pest species - welfare of**). Methods for controlling rodent pests include ingested poisons, contact poisons, fumigant poisons, live traps, lethal traps, sticky boards, repellents and preventing rodent entry to human habitations (Mason and Littin, 2003). Anticoagulant poisons are the most common form of control, being used in over 90% of rodent control situations in the UK and the USA. Some rats and mice have become resistant to anticoagulants but, in affected animals, anticoagulants can cause symptoms including inactivity, anorexia, bloody diarrhoea, breathing difficulties, paralysis and multiple haemorrhaging (painful in humans). These symptoms first appear 1-3 days after ingestion, and death occurs after 4-8 days. If sublethal quantities are ingested, symptoms can still occur in a milder form, and can persist for many weeks. Other methods are also reviewed by Mason and Littin (2003), who conclude that 'cyanide, alphachloralose, electrocution traps and well-designed snap traps all usually kill swiftly and with little distress' and that preventative

P.508

methods such as rodent-proofing are also humane and are under-used at present.

Rats and mice as laboratory animals

Mice are the most commonly used laboratory animal, followed by rats, and together they comprise about 85% of all research animals. There are now several thousand strains of domesticated mice and rats, including outbred, inbred, transgenic, knock-out and mutant strains. Most mice used in research are now genetically modified in some way. Welfare issues in laboratory rats and mice can arise from:

- genetic predispositions to certain defects, diseases or other disabilities;
- experimental procedures; or
- housing and husbandry.

In the European Union (EU), laboratory rats and mice are legally protected by Council Directive 86/609/EEC, using the **three Rs principle** as a framework for preventing unnecessary **suffering**. Rats and mice are protected in many other countries also but, at the time of going to press, they remain legally unprotected in the USA.

The specific welfare issues associated with genetics or experimental procedures vary enormously according to the research in question, so cannot be covered in this entry, but their welfare impacts can be assessed on a case-by-case basis. Flecknell and colleagues have described many behaviours to help researchers identify when rats and mice may be in pain (e.g. Roughan and Flecknell, 2003); analgesics are not routinely given to rodents after potentially painful procedures. For example, in studies published between 2000 and 2002, analgesics were reported to have been given only after 19.8% of potentially painful procedures (Richardson and Flecknell, 2005). Other species-specific welfare indicators can include vocalizations, stereotypic behaviours in mice (rats rarely perform these) and chromodacryorrhoea (a Harderian gland secretion) in rats (Mason *et al.*, 2004).

Some welfare problems associated with rat and mouse housing and husbandry include isolation of these social animals (but male mice sometimes show high levels of aggression if group housed); small cages; aversive handling methods; and lack of shelters, nesting material or any other environmental **enrichment** to create 'standardized' barren environments (Lawlor, 2002; Sherwin, 2002). The sensory environment can also be harmful to the animals (Burn, 2008): for example, normal lighting conditions can rapidly cause permanent retinal damage to the animals' eyes, being adapted for dim light conditions;

procedures are often carried out in the daytime when nocturnal animals would normally sleep; some laboratories (and homes) contain equipment that emits loud ultrasonic noise; and the homogenous diets provided in most laboratories provide no opportunity for the animals to nutritionally regulate or to gain positive experiences from gustatory diversity.

Rats and mice as companion animals

Despite the negative media portrayal of these animals, rats and mice are popular **pets**. Many websites and fan clubs exist extolling the virtues of these 'fun' and easily cared-for companions. So-called 'fancy' rats and mice are available with various coat colours and, for example, curly fur or 'dumbo' ears (positioned much lower than other rats' ears).

Yet, despite rats and mice seeming to be fairly lowmaintenance pets, their robust survival can conceal some common welfare problems. A major issue is that it is still very common to keep just one individual in isolation. Allowing rats or mice to breed can be a problem because it is often difficult to find homes for the pups, but keeping single-sex animals together can fulfil their social **needs**, such as playing and sleeping huddled together. Because rats and mice are nocturnal, social housing is particularly important for their long active periods at night, when their human owners cannot provide stimulation for them. However, aggression must be closely monitored, especially between male mice. The way that the individual animals are introduced is important for establishing a harmonious relationship and, if aggression is serious or persistent, the animals may need to be separated.

Cages should be provided with safe environmental enrichment and, particularly for rats, games and positively rewarded training can provide extra stimulation for the owner and the pet when interacting outside the cage. Rats and mice appreciate dietary diversity and can be fed kitchen scraps, but these should be chosen carefully; obesity is common in these pets, so high-calorie foods should be avoided, as should chocolate and dairy products because rats and mice lack the enzymes necessary to digest them properly.

Respiratory problems are common in these animals, and they should be checked regularly for behaviours indicating **pain**, **distress** or illness, including lethargy, stereotypic behaviour, sneezing or a hunched posture with raised (piloerected) fur. As with laboratory rats and mice, it is fairly rare for veterinary clinicians to prescribe analgesics for pet rats and mice suffering from potentially painful conditions (Roughan and Flecknell, 2003).

Rearing environment

The rearing environment is the environment an animal experiences up until maturity and includes all the stimuli, both social and non-social, that animals will be exposed to during this time. In natural environments, the rearing environment typically includes a mother and peers and a variety of changing environmental stimuli. In most cases, it is the mother that directs the offspring's attention to important or relevant environmental stimuli. However, in animal production there is often little or no contact with the mother and the environments tend to be relatively static with few opportunities to interact with environmental stimuli. Many domestic rearing environments are geared towards preparing the young physically for life in the later environments or reaching productivity criteria (such as **slaughter** weight) as efficiently as possible, with less attention paid to behavioural and psychological requirements.

Early-life experiences are very important to the development of normal behaviour patterns, and these experiences can have lasting effects throughout the life of the animal. **Imprinting** to different stimuli in the rearing environment occurs during early life. For example, many **precocial** species imprint on slowly moving objects that elicit a 'following response', and in natural environments this would encourage the young to follow their mother. There are **critical periods** or **sensitive phases** that occur in early life, where exposure to certain stimuli can result in lasting changes. Preferences for mates, foods, substrates, colours and so on are started in the rearing environment. For example, there is a period of time in the early life of songbirds during which the young birds can learn songs from their parents, even though the young do not start singing themselves until several months later. In some cases the preferences formed in early life can be altered by learning and experience, but in other cases they persist throughout life.

In intensive production environments, the rearing environment is dramatically different from that found in the wild (**see: Intensification of animal production**). These discrepancies between wild and human-made environments can lead to a number of behavioural problems and **welfare** concerns. One of the main problems in animal production rearing environments is the absence of a mother and associated early or artificial **weaning**. A well-known example of this is the experiments of Harlow and colleagues in which infant rhesus macaques were reared in environments with varying degrees of maternal and peer **isolation**. Animals kept in more isolated environments developed higher levels of stereotypic behaviour and **self-mutilation** behaviours than those reared with peers. These stereotypic and **abnormal** behaviours continued as the macaques aged and gave way to additional stereotypic and abnormal behaviours. Even **hand rearing** of animals alone can produce negative life-long changes in behaviour, such as heightened fear and aggression and poor parenting and social skills. This is a common problem in hand-reared exotic birds, which often imprint on humans as their sexual partners. Maternal deprivation can also affect the way an animal deals with stressors. For example, maternally deprived rats have been shown to adopt a reactive **coping** strategy compared with rats reared with their mothers that

adopted a proactive coping strategy. The presence of a mother also aids in behavioural synchronization compared with those reared without a mother.

In addition to the stress of being separated from their mother, some mammals also experience nutritional stress as they are changed from their mother's milk to a milk replacer. For example, lambs removed from their dams at 2 days of age had slower growth rates, higher cortisol levels and lower immune responses than lambs kept with the ewes and lambs fed a mixture of ewe's milk and milk replacer.

Wild-caught animals placed in captivity may display less stereotypic and abnormal behaviour than captive-born animals. However, the offspring of the former show similar levels of abnormal behaviour to the latter. This indicates the importance of rearing environment and parental care in the development of normal behaviour, and well-managed early experiences can help protect the animal from developing abnormal behaviours and a range of welfare problems later in life.

Rebound behaviour

Rebound behaviour refers to the increase in performance of a behaviour pattern after prevention of performance of that behaviour for a period of time. While some behaviour patterns may only need to be performed when elicited by external stimuli, such as anti-predator behaviour, others may need to be performed at regular intervals or certain rates (**see: Behavioural need**). It has been suggested that if the rate of performance of these latter behaviours falls below a certain preset level, there will be an increase in the amount of the behaviour performed at the next opportunity to compensate for the difference.

P.510

Animals in confined conditions can be limited or prevented from performing a number of normal behaviour patterns. However, the mere lack of occurrence of a behaviour pattern is not sufficient to determine whether there is a decrease in the animal's **welfare**. The demonstration of a rebound of the prevented behaviour patterns when the animal is removed from confinement can be used as an indication that the animals' needs may not be met in the management system and that their welfare may be compromised.

Reciprocity

Reciprocity in animal behaviour refers to the tendency to respond to social actions with similar social acts. Thus positive gestures are reciprocated as may negative ones. It is also referred to as a 'tit-for-tat' or 'equivalent retaliation' behaviour strategy. A misunderstanding of the need for reciprocity of **appeasement** and greeting gestures or the failure of carers to recognize such behaviours (e.g. moving slowly, looking away, yawning and indirect eye contact in dogs) can result in **agonistic behaviour**, ultimately culminating in overt **aggression** and an associated problem behaviour as a consequence.

Within **ethics**, reciprocity is sometimes referred to as the 'golden rule' of society and may be expressed as 'do to others as you would like them to do for you', and is a common code within social communities globally.

Recognition among animals

Recognition is such an extensive concept it is difficult to define. Researchers often define it operationally in terms of what their subject matter is, such as 'discriminative behaviour related to social categories' (Colgan, 1983), or defined 'by the nature of the objects being discriminated' (Sherman *et al.*, 1997). Recognition can be broadly thought of as *a unique response to something in the environment based on some form of previous experience*. Here, 'response' could be physiological and not externally manifest; 'something' could be as simple as a cell or as complex as a group of animals; and 'previous experience' could be at the level of the **genotype** (i.e. not necessarily during an organism's lifespan). An important point is that recognition is a fundamental and ubiquitous biological process that plays a key role in interactions at various levels of biological organization, from cells to whole organisms. At an organismal level, recognition in some form plays a central role in essentially all processes of assortment among animals (e.g. all social interactions including **mate choice** and **cooperation**). Recognition among organisms (e.g. self, kin, group, sex), particularly social interactions, is the focus of this item.

Social recognition behaviour is inextricably linked to Jacob Von Uexküll's original (1934) concept of **umwelt**, one of the founding concepts of **ethology**. In order to understand an animal one must understand how the animal perceives its surroundings: its umwelt. The animal's umwelt includes its perceptual world (**merkwelt**) and that within this world that is relevant (**wirkwelt**). The process of recognition defines the wirkwelt. Many aspects of heterospecific recognition concerning an animal's behavioural ecology (e.g. predator and prey recognition) occur at this level. An animal's social world may be understood in exactly the same manner, as nested within the larger perceptual framework defined by its umwelt. We can think of this as an animal's 'social umwelt': the social information that is: (i) available; and (ii) relevant. The resolution of **conspecific** identity (i.e. intraspecific social recognition) is among the most basic of such information. Although intraspecific social recognition by no means comprises all aspects of recognition behaviour by animals, it is recognition at this level that is most commonly addressed when the term recognition is used, usually in reference to **communication** about identity. A final important point here is that although all communication is not 'about' recognition (e.g. identity of the signaller), recognition necessarily defines and underlies all communication. Recognition can thus be thought of as the 'carrier wave' of all communication behaviour among animals.

Approaches to the study of recognition

For the purpose of study, recognition behaviour can be broken into three essential components: production, perception and action (Sherman *et al.*, 1997). Although all studies necessarily focus on one or a combination of these aspects, few do so explicitly. The result is that distinctiveness at whatever level of organization is being studied (e.g. individual, group, etc.) is often confused with recognition ability. That an animal has a distinctive trait (e.g. vocal individuality) does not confer recognition ability. The trait must also be perceived and acted upon. As a result, many investigations of recognition behaviour use **experimental 'playback'** paradigms or procedures in order to invoke reactions.

In order to compare the array of approaches used in studies of recognition behaviour it is important to distinguish between those that take evolutionary or 'ultimate' perspectives as compared with mechanistic or 'proximate' perspectives. Studies focusing on proximate forces acting on recognition behaviour are likely to be testing for the existence of recognition, the cues used or the level of resolution achieved. Cues that animals use for recognition of conspecifics can be grouped into four general categories: spatial location, familiarity, **phenotype** matching and allele/genotype matching (although beware, as many researchers use these terms in their 'ultimate' perspectives on recognition: see below). The salient sensory cues used for recognition vary considerably among taxa. Although the process is often multi-modal, most studies have focused on the acoustic/auditory channel using a limited number of taxa. A substantial amount of research has also focused on olfactory

recognition, mostly with social insects and mammals. In comparison, there has been considerably less research on electrical and visual recognition, and very little in the area of cross-modal comparisons of recognition.

Different organisms are capable of different degrees of recognition, referred to here as *recognition resolution*. The ability to resolve individuals, as compared with groups (e.g. castes of social insects, breeding colonies, etc.) or species, appears to be mostly limited to birds and mammals. Tests of individual recognition often focus on parent-offspring recognition or neighbour-stranger (Dear Enemy) recognition

P.511

in territorial animals. Often, however, true individual recognition in these circumstances is unnecessary. Beecher and colleagues (1989) made the point that true individual recognition is the ability to discriminate each individual in a group from every other individual. Functional individual recognition, in contrast, is the differential treatment of an individual based on individually distinctive cues. Individual recognition capabilities can be further thought of in terms of lateral and longitudinal resolution. *Lateral resolution* refers to the number of individuals one is able to resolve at a given point in time (e.g. immediate kin, more distant kin, cohort members, etc.). *Longitudinal resolution* refers to the durability of recognition over time (e.g. how long it lasts).

Identifying selective pressures acting on recognition behaviour invokes an ultimate perspective (i.e. an evolutionary timeframe) on the subject. Sherman and colleagues (1997) developed such a theoretical framework based on the nature of the objects being discriminated. Two basic and non-exclusive categories are whether the 'objects' are potential mates or whether they are kin. **Kin recognition** is the necessary ingredient for nepotism, where genetic relatedness is used to explain cooperation through kin selection. Recognition between parent and offspring - maternal recognition in most mammals - is a special subset of kin recognition. Mate recognition, on the other hand, is key to assortative mating and possible sympatric speciation, and to the process of sexual selection via mate choice. The two types of recognition overlap in the area of optimal outbreeding: obtaining a balance between **inbreeding** and outbreeding when selecting a mate.

In summary, recognition processes are fundamental to every aspect of biology. The patterns and mechanisms of recognition behaviour in animals can be approached from many different and often interrelated perspectives. Taken together, they are a critical part of understanding the behavioural ecology and consequently the conservation of any species or species complex.

Redirected behaviour

A redirected behaviour is one that is directed towards an apparently inappropriate target. This may occur as a response to a stimulus where the primary target for the behaviour is unavailable (**see: Frustration**). For example, **wood chewing** in

horses may represent redirected grazing behaviour. Redirected **aggression** is aggressive behaviour directed towards a target other than those engaged in the confrontation, possibly because it is not possible to reach those. Redirected behaviour differs from **displacement behaviour** in that, although both seem to occur when the animal is thwarted in its original activity, in redirected behaviour the target for the behaviour is substituted rather than the behaviour itself.

(KT)

See also: **Emancipation**

Reflex

Reflexes are simple reactions to stimulation involving automatic, involuntary and fixed movement patterns in response to external stimuli, such as blinking or sneezing, and can also be classified as fixed-action patterns. The sense organs that detect the stimulation send messages to the **central nervous system**, which sends responses directly to the effector organs. Reflexive reactions do not require higher cognitive processes and thus their measurement is not considered a good indicator of **sentience** in non-human animals.

(LMD)

Regan, Tom

Tom Regan (b. 1938), Professor of Philosophy at North Carolina State University, USA, is a leading exponent of the **animal rights** movement in the USA. He denies that human beings are unilaterally significant from a moral point of view by arguing against the belief that 'animals are here for us' as mere resources. In contrast to **utilitarianism**, Regan applies a *strong* rights-based perspective to our treatment of animals and concludes with an abolitionist stance towards the use of animals in agriculture, biomedical research and sport **hunting**.

Regan rejects the idea that acts are morally right or wrong as a function of their consequences. For example, even though the use of animals in biomedical research has the potential to produce good consequences for future patients (animal and human alike), Regan denies that this is adequate justification for harming animals' interest in continued existence.

Regan sets out in *The Case for Animal Rights* (1983) and *Defending Animal Rights* (2001) the nature and content of moral respect. His view of respect accords with the philosophical rights view espoused by rights theorist Joel Feinberg (1984), who contends that 'To have a right is to have a claim to something and against someone, the recognition of which is called for by legal rules or, in the case of moral rights, by the principles of enlightened conscience'. A moral right serves as a *valid claim* that makes demands of others. Rights serve to protect or promote individual integrity and vital interests in self-determination, physical security and life. As a valid claim, a right serves as a *protective barrier* or 'trump card', shielding the rights-bearer from unjustified violation or infringement of their person or interests by others.

Where animals are concerned, Regan understands these demands to include, at minimum, *negative or non-interference* rights, whereby moral agents are obligated not to thwart animals' interests. Claim rights may also encompass *positive* rights, which are understood as obligations to provide conditions that *benefit* the rights-holder. Regan is less clear whether animals can demand that we actively take steps to benefit them. One consequence of Regan's view is that if an animal has the right to life, for example, then it would be

P.512

morally egregious for us to kill it for our benefit, especially if there are viable vegetarian options available and it is not a matter of survival that we have to eat animal protein. Animals may also not be used as organ and tissue donors just because people would benefit from their deaths.

Regan melds the concept of inherent value with certain psychological properties of the beings in question, and the notions of moral respect and rights. He argues that certain animals, *subjects-of-a-life*, possess certain moral status-making features that make them inherently valuable. They are individuals who possess

beliefs and desires, perceptions, memory, and sense of the future, including their own future: an emotional life together with feelings; an ability to initiate actions in pursuit of their desires and goals; a psychophysical identity over time; and an individual welfare in the sense that their experiential life fares well or ill for them, logically independently of their utility for others, and logically independently of their being the subject of anyone else's interest. (Regan, 1983, p. 243)

Regan contends that *moral agency* is not a prerequisite for membership in the moral community. By ‘the respect principle’ outlined in his discussion of rights, he concludes that all subjects-of-a-life have equal rights to respectful treatment and to be protected from harm that cannot be overridden in order to promote the good of some other beings.

His focus on interspecific psychological similarities also makes use of the argument from *marginal cases*. If we think that human moral subjects, like infants and ‘nonparadigm’ or ‘misfortunate’ human beings, deserve equal moral respect and equal moral consideration just like adult ‘paradigm case’ human beings, then there ought to be similar obligations to respect the lives and inherent value of all subjects-of-a-life who have similar moral status-making features, regardless of species. Regan thinks that there is no non-bias, human-centric ground for attributing rights to ‘marginal’ humans that would not also apply to many animals. Moral rights are something you either have or you don’t: they are ‘all or nothing’, otherwise the notion of equal consideration would be subject to arbitrariness. Members of the class of subjects-of-a-life are (at least) all normal mammals greater than a year of age. He leaves the line between those animals that are subjects-of-a-life and those that are not intentionally vague, awaiting better insight into animals’ minds to help provide guidance.

Regan acknowledges that conflicts of rights between rightsholders do occur. He offers two ways in which rights may be prioritized:

1. The *mini-ride principle*: in the case of comparable harms, we ought to override the rights of the fewest number of individuals. This appears to have a utilitarian flavour to it in practice.
2. The *worse-off principle*: in the case of non-comparable harms, we ought to avoid harming the individual who will be worse off, i.e. more basic rights trump trivial or peripheral ones, irrespective of the species of the rights-holder.

Reinforcement - types of

The actions an animal performs can be associated with various consequences. There can be no significant consequence to the action, which means there is no feedback that alters the likelihood of the behaviour in similar circumstances. An **aversive** consequence will reduce the likelihood of the action being repeated, while the opposite will increase the likelihood of the action being repeated. In this context, the term ‘reinforcement’ is used in different ways by different authors and this can lead to some confusion. In its broadest sense, the term is used to describe any outcome of the behaviour that has motivational significance, and thus the term ‘aversive reinforcement’ is synonymous with **punishment** (reinforcing aversion towards performing the behaviour), and the term ‘appetitive reinforcement’ synonymous with the narrow-sense definition of reinforcement, which is the focus of this entry. This narrow-sense definition restricts the term to any associated event that increases the likelihood of the preceding action being repeated.

Reinforcement in this narrower sense can occur when an event or object is presented to the animal (e.g. food is acquired, access to a desired activity is gained). This is known as positive reinforcement. Alternatively, it can occur when an undesirable event or object is removed from the animal (e.g. some level of restriction is lifted). This is known as negative reinforcement. By definition, these events can only be considered reinforcers if the action that precedes their presentation increases in frequency or probability. It is for this reason that the term positive reinforcement is preferable to reward, since the latter could imply compensation for the action, without necessarily altering its probability in future, i.e. in human

terms we might think of a reward as a 'thank you' message, while a positive reinforcer is a message that says 'if you do it again, then you might get more'.

For an event to serve as a reinforcer for an action it needs to be associated with the animal's behaviour, and there are two important considerations in relation to this: **contingency** (the predictability of the association) and **contiguity** (the closeness of the two events in time or space). These rules of association can be used in a number of ways to the benefit of behaviour modification, as well as for the teaching of very specific actions. For example, during the procedure known as differential reinforcement of other, any action except the unwanted action may be reinforced, which leads to an increase in a variety of actions perceived as desirable or appropriate and a simultaneous reduction in the unwanted action without the need for reinforcing a single action incompatible with the unwanted action.

Reinforcement can be presented according to different schedules (response contingencies), and these will influence the preceding behaviour in different ways. If a reinforcer is presented every time an action occurs, this is referred to as a continuous schedule of reinforcement and will typically lead to the fastest acquisition of new behaviour. However, when a continuous schedule of reinforcement is used and reinforcement

P.513

is then withdrawn, **extinction** of the behaviour will occur rapidly. Intermittent schedules of reinforcement on the other hand, where not every response is reinforced, may lead to a reduced rate of acquisition of the behaviour but, in most cases, will increase the behaviour's resistance to extinction (a phenomenon known as the partial reinforcement effect or PRE). A number of different intermittent reinforcement schedules are described:

- Fixed ratio schedule: a set number of actions need to be performed for each reinforcer. For example, every third response is reinforced.
- Variable ratio schedule: a variable number of actions need to be performed for each reinforcer; however, they average at a given ratio. For example, on average every third response is reinforced.
- Fixed interval schedule: a response is only reinforced a set time after the previous reinforcement has been delivered.
- Variable interval schedule: a response is only reinforced on average a set time after the previous reinforcement; however, this time is variable.

Each of these schedules will see response curves that differ in key aspects. Typically, there is a decline in the rate of performance (post-reinforcement pause) after reinforcement, and this is greater on a fixed compared with a variable schedule, although the rate increases markedly towards the time of expected reinforcement in a fixed schedule.

Outside the laboratory in a training context, it is most common to find the use of a continuous schedule used for the acquisition of a response and then a variable ratio schedule used for maintenance. For the maintenance of high-level performance differential reinforcement may be used, in which only behaviours with specific characteristics are reinforced for example, behaviours with a particularly short latency or those that are particularly satisfactory for some other reason. This is a form of intermittent reinforcement in which the physical characteristics of the preceding behaviour determine the probability of reinforcement and, as the animal approaches a continuous schedule, the standard is raised higher. For most behaviours a degree of extrinsic reinforcement is required (such as the provision of food or a toy) for their maintenance, although some behaviours are associated with intrinsic reinforcement (such as **play**). There is some debate over whether the acquisition of information can have intrinsic reinforcing value (**see: Contra-free loading**).

Elimination of reinforcement, in the form of its complete omission or a significant decline in the rate of reinforcement, induces ratio strain, which is characterized by a disruption in the normal pattern of responding and may ultimately lead to extinction of the response. Prior to extinction, the behaviour may intensify for a short while during this period of nonreward, before it rapidly declines. This increase in the behaviour is called an extinction burst and is believed to arise as a consequence of the frustration associated with the decline in reinforcement. The absence of an expected reward may be considered a form of negative punishment.

In most cases where behaviours are taught to animals it is necessary that they be performed at the request of a person. This process is popularly referred to as cueing a behaviour or putting a behaviour on cue, and is an example of **stimulus control**. Stimulus control exists when behaviours, which have been taught through reinforcement, are performed differentially according to the stimuli present. The cue is simply a stimulus that tells the animal that reinforcement is available should a specific action be performed. In the absence of the cue, no reinforcement is available, i.e. reinforcement is not only a response-contingent event but also a stimulus-contingent event.

Reinforcement may be delivered by either primary or secondary (or tertiary) reinforcers. A primary reinforcer is something that is typically reinforcing for the species (a natural reinforcer) - for example food, water or copulation. The significance of a secondary reinforcer on the other hand needs to be learned by association with a primary reinforcer (and that of a tertiary reinforcer by association with a secondary reinforcer, and so on). A phrase such as 'good dog' has no intrinsic value to a dog, neither does the sound of a clicker (commonly used in pet training (**see: Clicker training**)) or a whistle - the secondary reinforcer commonly used in marine mammal training. The value of a secondary reinforcer arises as a result of its classical conditioning with a primary reinforcer (**see: Conditioning - types of**).

A practical advantage gained by using a secondary reinforcer is the ability to increase the temporal contiguity between the action and the delivery of reinforcement. Some actions are taught where the practicality of delivering a reinforcer immediately after the desired response or close to the point of the desired response is difficult. For example, when teaching an assistance dog to cross the room to turn on a switch, the desired action takes place at a distance from the trainer. When using a secondary reinforcer, such as a clicker, the clicker can be sounded at the moment the action is performed (high temporal contiguity) and the secondary reinforcer can then be delivered later in time and in a different place, if a delay has been built into the association between the secondary and primary reinforcers.

Not all reinforcement is deliberate, and any action that is maintained in an animal's behavioural repertoire may be being reinforced in some way. This is important to consider when behavioural change is desired and behaviour modification is implemented. For example, for some dogs even eye contact with a person can reinforce a desire for social contact and can be the reason an attention-seeking behaviour is maintained.

Reintroduction

Reintroduction is an attempt to establish a species in an area that was once part of its historical range, but from which it has since been extirpated or become extinct (IUCN, 1998). The concept has been with us long before it became associated with **endangered species**. For example, pheasants and waterfowl have been raised in captivity for hundreds of years to restock wetlands and other areas for sport **hunting**. For species

conservation, reintroduction is often seen as a last resort for establishing or reinforcing a wild population. Reintroduction programmes may involve translocating wild animals from one area to another, often from an area where they are plentiful to an area where they formerly ranged (**see also: Translocation**).

It may involve removing animals when they are particularly vulnerable to natural threats such as **predation** or flooding, maintaining them in **captivity** for a period of time and returning them to the capture area when their chances of survival are greater. For example, caiman and sea turtle eggs are removed from nests in the wild, incubated in protected areas and the young are then released near the nesting site when they are large enough to have a higher probability of survival (**see also: Headstarting**). In this way, the young reinforce wild populations. Reintroduction programmes may also include breeding and rearing animals in captivity over several generations. This may be due to: maintaining genetic diversity in the wild population by creating a genetic reservoir in captivity; the lack of adequate conditions in the former range to release the animals; or the wild population being so small that the only way to protect it from **extinction** is to bring the remaining individuals into captivity for **captive breeding programmes** (e.g. the California condor, *Gymnogyps californianus*).

Reintroduction programmes are often expensive, time-consuming and unsuccessful. They depend on scientific research to determine whether reintroduction is feasible, the cooperation of stakeholders (i.e. governments, local communities, non-

governmental organizations), public relations and conservation education, a commitment to long-term funding and post-release monitoring. To a large extent, successful reintroduction depends on reducing or removing whatever threats had reduced or eliminated the wild population. Threats can include habitat loss, poaching, predation, **disease**, competition with introduced non-native species and human–animal conflicts. However, if the threats can be ameliorated and the impacts of reintroduction on the release animals and the ecosystem in which they will be released are evaluated scientifically, the programme stands a much better chance of success. The behaviour of release candidates is critical to ensure survival. This entry will focus on the importance of behaviour in reintroduction.

Effects of captivity

From a historical perspective, two generalities can be made. First, more behaviourally ‘hard-wired’ taxa such as fish, amphibians and reptiles tend to be reintroduced more successfully than birds and mammals if anthropogenic causes of decline are managed (e.g. collection of specimens for food or the pet market). Generally, these animals reproduce early in life, produce many young at a time and do not require parental care. Thus, it does not take many years for these animals to establish themselves. The second generalization is that wildborn animals tend to survive better when reintroduced than those that are bred in captivity. This is particularly true for long-lived mammals and birds. These k-selected species take several years to become reproductively mature, and offspring per reproductive season are few. Such long-lived animals also have long periods of parental care. Thus, these animals may spend many years in captivity before sufficient numbers are available for reintroduction. Behavioural variability from long periods in captivity or generations of offspring produced from captive breeding are important in reintroduction programmes because traits necessary for survival may be under-represented.

In **zoos** and aquariums, reintroduction species are increasingly provided captive environments that stimulate the full range of species-appropriate behaviour. Opportunities can be created through environmental enrichment such as group housing for social species, providing a variety of foraging options, topography and manipulanda (e.g. twigs, stones) (**see also: Enrichment**). Although the full behavioural repertoire may be represented in captivity, the proportion of time spent performing the behaviours and the frequency of occurrence may not be what is required to survive in the wild. Behavioural research, including the development of **ethograms** in captivity and the field, can assist in preparing release candidates.

Captivity can also affect **tameness**, migration (no knowledge of traditional migratory routes), philopatry (tendency to return to the same breeding area or colony), social skills for reproduction and establishing territory. Release candidates must be able to avoid predators, acquire and process food, interact socially with **conspecifics**, find or construct shelters or nests, move on complex terrain and orient and navigate in a complex environment. The Universities Federation for Animal Welfare (UFAW) reintroduction guidelines (1992) suggest that the captive environment should mimic the wild as much as possible to allow the individual animals to learn and exhibit their full range of behaviours necessary for survival.

Reintroductions of captive-bred animals should not proceed without first reviewing the scientific literature and conducting field studies to determine which behaviours observed in the wild should be encouraged in captivity. Another way to identify potential behavioural challenges that may impact survival is to conduct experimental reintroductions with similar, but more common, surrogate species to develop the expertise and methodology needed for the release programme species. For example, the Siberian ferret (*Mustela eversmanni*) was used as a surrogate for the endangered black-footed ferret (*Mustela nigripes*), the Andean condor (*Vultur gryphus*) for the California condor and the greater sandhill crane (*Grus canadensis tabida*) for the whooping crane (*Grus americana*).

Rearing and release methods

Reintroduction programmes often manage small populations of the endangered species in captivity. In order to produce a large number of offspring (usually from a small founder stock) for the reintroduction programme as well as to manage the genetic diversity of the captive population, it is not always possible to have all offspring raised by their parents. In the whooping crane recovery programme, in order to increase the number of chicks produced per year, parents are encouraged to lay a second egg clutch (double clutching) by removing offspring from the first clutch. Other chicks are removed because parents may not provide appropriate care or may be too aggressive towards the young. Thus, some chicks are hand-reared by caretakers. Caretakers wear costumes and use puppets that resemble the parent. This also serves to keep the chick from **imprinting** on humans.

In the wild, **parental investment** is important to the survival of **precocial** young. Depending on the species, parents feed the young, identify appropriate food items and

demonstrate how to handle them, and protect the young from predators. Young also learn predator recognition, nest-building skills, offspring rearing, migratory routes and appropriate **vocalizations** from parents. However, the importance of parental rearing in reintroduction programmes is variable. A potential drawback of parental rearing in captivity is that the parents may behave differently from their wild counterparts, particularly if they were not reared by wild founder stock. Some offspring may learn inappropriate behaviours such as stereotypic pacing. With hand-rearing, humans decide what behaviours are important to survival in the wild and encourage these behaviours by becoming the surrogate parent. Puppets, mannequins, costumed caretakers and adult conspecific models are often used to teach young, hand-reared animals to locate food and water, encourage flocking and social behaviour and teach parenting skills.

Young may also be cross-fostered or reared by adults of a similar, but more common, species. Exposure to predators, environmental enrichment and rearing with adult models in view are husbandry techniques designed to provide exposure of the young to novel stimuli that may be encountered in the wild.

Regardless of rearing method, for some species, captive rearing methods do not affect post-release survival as much as the animal's adaptability to challenges at the release site. Finally, animals are individuals. Some may be unusually inquisitive and others may be very aggressive. Generalizations may be made by species, release group or rearing method, but some animals will inevitably be better release candidates than others.

The elimination of tameness and appropriate responses to predators are important factors in behavioural modification in captivity for many species. Tameness is the absence of aggression towards humans and tolerance to **handling**. The effects of tameness on survival are mixed. It has caused human-animal conflicts such as released California condors perching on suburban homes and destroying roof shingles or puncturing car tyres. Conversely, tameness allows for animals to be easily recaptured after release, led to safer areas or for more effective manipulation for minor veterinary procedures such as inoculations.

Release candidates must sometimes be taught how to behave to evade predation (**see also: Anti-predator training**). **Predator avoidance** behaviour may involve finding habitat that is inaccessible to the predator or adopting a body position such as crouching. In captivity, predator avoidance can be encouraged by providing the individual with a psychologically traumatic experience such as controlled exposure to a real predator. Techniques have involved the use of dogs, taxidermy models, falconry birds and costumed or unclothed humans. Caution must be used when including anti-predator training in a reintroduction programme so the individual does not habituate to the predator or become injured or killed, thus removing it from the pool of release candidates.

Typically, animals are 'hard released' or 'soft released'. Hard-released animals are simply transported to the release site and released. This works well with r-selected species like insects, amphibians, fish and many reptiles. Most mammals and birds are soft released. Soft-released animals are placed in pens at the release site for a period of time before being released. The soft-release method gives the release animals time to adapt to their new surroundings. The pen provides the animals with opportunities to forage for local food items, navigate on new substrate and interact with resident animals without risking predation or injury from aggressive conspecifics at the site. It also gives managers the ability to observe the animals to determine whether any final intervention is needed before release.

Behaviour is also considered in the timing of release. The season of release is important especially if the resident wild animals are territorial (e.g. breeding season) or the food supply is low (e.g. dry season). Another consideration is age. Birds are usually not released until they are at least fledged and able to fly with a flock. Mammals are not released before they are weaned. A further behavioural consideration is the composition of the release group. Some animals are socially solitary and others must be in groups of a certain size, with the appropriate age structure and sex ratio.

The role of applied ethology studies

While science has been used extensively to develop population genetic management strategies, veterinary care and health monitoring techniques and propagation methods, applied ethological studies are far less prominent. This is understandable because endangered species are often on the brink of extinction, sample sizes are small and recovery teams often operate in a crisis mode. Behavioural studies of reintroduction species are time-consuming, require regimented experimental conditions and may involve some degree of risk to the release candidate (i.e. **stress**, **pain**, suppressed reproduction). Using more common surrogate species, however, can minimize risk to the reintroduction species (but animal **welfare** risks to the surrogate must still be considered). Rigorous systematic studies involving behavioural observations pre- and post-release have helped to determine the optimal rearing conditions and release strategy. Behavioural research has also helped identify the best release candidates. Wildlife managers and biologists have collaborated in determining which behaviours are most

essential to the programme. If there are advantageous behaviours that are being selected against in captivity (such as vigilance), they can be identified, studied and encouraged. Important areas of study include predator recognition and evasion, development of parental behaviour or **foraging behaviour** and **reproduction** and **social behaviour**.

A study of behaviour in captivity cannot predict optimal behavioural strategies in the wild without comparison to field studies. Ideally, studies should be conducted at rearing and release sites. If there is a lack of field studies or if it is difficult to observe animals in the wild, it may be necessary to remove individuals from the wild for observation in a naturalistic enclosure. This can be done *in situ* or at a remote facility.

The following are considerations when planning an applied ethology study with a reintroduction species:

1. Commitment of decision makers. Funding, personnel and material resources must be assured for the duration of the study. In addition, there must be commitment to the agreed upon sample sizes and study design.

P.516

2. Statistics. The experimental design and statistical analysis should be developed a priori. This includes appropriate sample size and replication. In some instances, it is difficult to propagate large numbers of some species in captivity necessary to have a statistically useful sample size without involving multiple captive-breeding institutions. In addition, study results may be affected by year (i.e. drought, change of release site). Without repeating a study over the course of years, it is difficult to determine whether results are due to year effects or whether they represent typical behaviour of the study species.

3. Wildlife management. Release site selection, method of release, timing of release and post-release monitoring may vary from site to site or year to year based on decisions made by wildlife managers. Such variability may need to be reduced to produce sound study results.

4. Captive management. Conditions in captivity can vary due to the number of pens available, removal of animals from the study for veterinary purposes, social behaviour of penmates and other factors. This too should be considered to control for variability in the experimental design and interpretation of results.

5. Animal welfare. With small sample sizes, the survival of every individual is important. However, to determine best release methods or release candidates, some studies may need to involve physical risks to some animals. Humane endpoints need to be considered.

6. Peer review. Many proposed studies are reviewed and approved by outside scientists, as well as those knowledgeable about the study species (such as Recovery Team members), and a statistician.

7. Publication of results. There are far too few reintroduction-related studies in the scientific literature. Regardless of what the results are, it is important for researchers to know, for example, what rearing and release techniques improved post-release survival and what did not. Descriptions of methods, including rearing and release, statistical design and results, should be as detailed as possible so that the study can be replicated or comparisons can be made with other studies.

A note on animal welfare and ethical dilemmas

There are important animal welfare and ethical considerations with reintroduction. In captive population management, decisions with welfare implications include: (i) deciding which animals should be removed from a group and relocated to another facility for **breeding (see: Transport)**; (ii) separating mothers from young; (iii) how and where to house offspring that are surplus to the genetically managed population; and (iv) what to do with post-reproductive animals. Some animals may be artificially inseminated, and may be deprived of the experience of natural breeding. As discussed above, training avoidance behaviours such as predator evasion or deterring the animal from interacting with the human environment may involve aversive conditioning such as mild shock, loud noises or pursuit. The welfare of prey animals should be considered in preparing predators for reintroduction. If a captive-bred predator will need to kill live prey post-release, it must be taught to recognize, capture and feed on live animals. Prey animals will defend themselves and can pose significant dangers to predators (e.g. through biting, scratching, kicking, etc.).

From an animal welfare perspective, the **well-being** of the prey animal is just as important as the well-being of the predator. This is a critical difference between conservation and welfare philosophies. From the conservationist's perspective, the more endangered species is accorded a comparatively greater value than that of the more common species (**see: Ethics**). Conservationists value naturally occurring biological diversity and understand the interdependency of species; the loss of one species can result in the loss of others. This is in contrast to animal welfare (and **animal rights**) philosophy,

which focuses exclusively on individual animals. Thus, ethical considerations must balance the welfare of individual animals versus their value to a reintroduction programme and conservation.

Defining reintroduction success

The success of a reintroduction project may be measured by a series of benchmarks: length of time the animal survives in the wild, breeding success, survival of offspring or when a population becomes independent from human support. Some view a programme as being successful either when the wild population reaches 500 individuals that do not depend on human support or if demographic analysis predicts the population to be self-sustaining.

Rejection

Rejection of the young animal by its mother is a natural process, by which **weaning** is achieved, but in most if not all species of farmed mammals, individual mothers may reject the neonate. This is most common with the first **parturition**, and farmers can often overcome it by confining the mother with her newborn, or restraining her. If this fails, young can often be fostered (**see: Fostering**); this often happens spontaneously in **pigs**, which are particularly accepting of the offspring of other females. Fostering lambs and calves is very commonly done by farmers, though seldom achieved with **horses**, where foal rejection can be a troublesome problem. **Breeds** differ in this aspect of maternal behaviour - this is evident in horses, and some breeds of **sheep** are more likely to reject their lambs than others. Among British breeds, the Suffolk (a breed associated with relatively intensive, lowland sheep farming) is more likely to reject her lambs than the Scottish Blackface (a hill breed, developed in a harsher environment). A cow is more likely to reject her calf if it is her

first, and some of the behaviours she may show suggest that there is an element of **fear** of the newborn. Another cause could be a failure of the **bonding** process. In all species so far studied, there is evidence for a **sensitive phase** soon after birth, when the mother and neonate bond together, and this could easily be disturbed in crowded or **stress-inducing** conditions.

Relational ethics of care

This is the ethical position according to which special emphasis is given to responsibilities incurred due to relationships formed with others. Examples include spousal relationships, parent-child relationships and the **human—animal bond**. In the latter case, acceptable animal use is contingent on there being a sustained effort to promote mutually beneficial relationships and husbandry conditions that foster attitudes of caring.

Relationship

The term ‘relationship’ describes the connection between two or more individuals or things. It can describe the extent of the association and influence of one situation on another, for example the relationship between body size and heat loss. Relationships between variables may be measured and represented as an equation, e.g. the simple linear regression equation: $y = ax + b$, with one variable (y) being dependent on the other (x).

The term ‘relationship’ may also be used to describe the connections between individuals or groups of animals. These may be defined in terms of genetic similarity between individuals (e.g. **kinship**) or the influence of one group of individuals on the population of another (e.g. predator-prey relationships). ‘Relationship’ is commonly used to describe the quality and quantity of the social interactions between individuals or groups of individuals.

Relationships between individuals of a social species

The relationships between individuals of social species have been explored in detail by zoologists such as Goodall, Harlow, Hinde and Stevenson-Hinde in the 1960s and onwards. Their primary interest was the social relationships of primates, how these could be described and how they compared with relationships among humans. Their observations were based on individuals within natural social groups in **field studies** (Goodall) and on separation experiments in the laboratory (Harlow). The results of their research underpin the basis of our understanding of animal relationships today.

Hinde defined relationships as ‘a series of interactions that occur over time between two individuals that are known to each other’ (Hinde, 1987). An interaction is a series of interchanges that occur over a shorter period of time; for example, an aggressive interaction may involve posturing and threatening interchanges. These interactions can be described in terms of their type (e.g. biting or kicking), their quality (e.g. intensity or ferocity) and duration and can be used to form a picture of the kind of relationship between the two individuals. Within a social group or network there will be a complex of relationships, with each individual having a relationship with other individuals - possibly everyone - in the group.

Early attempts to describe the relationships between individuals of a group tended to be oversimplistic. For example, individuals in a group would be placed in a linear **hierarchy** from the most dominant to the least (e.g. pecking orders in horses). Group dynamics in many species are now thought to be more subtle, with dominance of one individual over another depending on more fluid variables such as the context or resource, in addition to more static ones such as the individual's age or size. It is also recognized that relationships between individuals occur over many dimensions and, for a more complete picture, a number of these need to be measured. For example, looking at the 'nearest neighbour', i.e. the individual in the closest physical proximity to the individual in question at any given time, within groups of horses for example, has shown that individuals have preferences for certain individuals and these 'friendships' may more accurately portray the relationships within a herd than interactions relating to dominance. In addition, looking at the relative frequency of interactions, e.g. how many times A helps individual B out or the number of times B solicits help from A, may more accurately describe the strength of the relationship between individuals. This tool has also been used to look at relationships between individuals that are based on reciprocity, for example cooperative alliances between male baboons (reciprocal **altruism**).

The relationships between individuals may also be defined by the role each individual plays within the group. A mature female within a band of horses may, for example, have a leadership role that is characterized by being the individual that initiates the moving on of the group towards richer

P.518

pasture or water. A mature male may have the role of primary defender of the group. Roles may not be static, and aggressive displays may signify a change in the roles between individuals.

Human-animal relationships

The relationship between humans and animals varies enormously depending on the species in question and the context. Perhaps the closest desirable relationship is that between a **pet** animal and its human 'owner'. Several aspects of this relationship have been investigated, including: (i) how it evolved (**see: Domestication**); (ii) the ways in which it can be described (in terms of love, trust, obedience, etc.); (iii) the benefits to the human of this relationship (in terms of health and mental wellbeing); and (iv) the influence of the human's characteristics and attitudes on the pet (particularly in terms of welfare and behaviour problems).

The relationship between pet and owner seems most closely to resemble a surrogate parent-child relationship, but the two types of relationship do differ. Infantile characteristics such as friendliness, dependency and playfulness are often among those favoured by the owner in their pet. Some **companion animals** retain specific infantile behaviours, for example, kneading by cats when being held. However, a degree of **reciprocity** is also apparent in the human-cat relationship: for example, the cat may terminate the relationship if the human does not fulfil their role, e.g. by providing food. The relationship between a dog and its human owner is one of the closest **human-animal bonds** and the most long-standing, since dogs were the first animals to be domesticated several thousand years ago.

Attachment

A particularly strong relationship may be described as '**attachment**'. This can be defined as 'an affectional tie that one person or animal forms between itself and another specific individual, which binds them together in space and endures over time' (Ainsworth and Bell, 1970). Behaviours that indicate that one individual has an attachment bond with another include proximity seeking and maintenance towards the attachment figure, protestation and following when they are leaving their sight and greeting upon their return. Such attachment behaviours are adaptive in that they ensure that the individual remains in familiar company and is therefore more likely to be protected from danger. Attachment typically describes the parent-child relationship but may be applicable to other relationships, i.e. between mating pairs, and occur in other non-human species.

Features of attachment are preference for the attachment figure, which assumes the ability to discriminate and respond differentially to the attachment figure and response to separation from and reunion with the attachment figure that is distinct from responses to others. Attachment has an internal structure that endures over time, even during periods when attachment behaviours are not being activated. Ainsworth devised the 'strange situation test' to activate these behaviours by subjecting infants to periods of separation from their attachment figure (their mother) in a strange environment (Ainsworth and Bell, 1970). This technique has since been used with dogs and results suggest that attachment may also describe the relationship between a dog and its owner (Topal *et al.*, 1998).

Releasing factor

A stimulus that triggers an **innate releasing mechanism** resulting in the performance of a fixed action behaviour pattern (FAP). 'Releasers' are specific events or observations (also known as sign stimuli - although reserve the term for releaser for social cues, and use sign stimuli to refer to physical cues) within a more complicated context that can be identified as the initiator of the FAP. For example, **Niko Tinbergen** found the presence of a red belly on an approaching individual to be the releaser for aggressive behaviour in male stickleback fish.

Reliability

Reliability refers to the quality of a test or measuring procedure. A test or a procedure is considered reliable to the extent that it yields the same result on repeated trials. Reliability may require one observer to obtain the same results over time (longitudinal reliability, or repeat reliability) or may focus on the ability of different observers to acquire the same results (**inter-observer reliability**).

Religious slaughter

Some religions require food animals to be killed by a specific, traditional method, the protocol for which may be both rigid and immutable. These protocols were described in ancient religious texts and, given the requirement that an animal is

unblemished at the time of **slaughter**, had the aim of maximizing food safety and moral respect for the animal while minimizing suffering in the context of the standards of the time.

The traditional Jewish method of slaughter, *shekita* (or *shochetim*), requires the animal to be conscious at slaughter, restrained in a specialized pen with the head held fast. A

P.519

transverse, reciprocal cut is made in the neck using a long, very sharp and undamaged blade with an uninterrupted motion. The animal is then restrained until it has bled out. **Sheep** may have the wool shaved from the neck to facilitate the cut and are restrained on their back in a cradle. All followers of the Jewish religion are required to eat meat killed by only this method. Some premises may administer an immediate post-cut stun for **cattle** where rabbinical approval has been given.

The traditional Muslim method of slaughter, *halal*, is in many respects similar to *shekita*. However, in *halal slaughterhouses* in some countries, where consumers are concerned about animal **welfare**, pre-stun methods that do not kill the animal and where the heart continues to beat have been deemed acceptable by religious authorities.

In many Western countries, slaughter without prior stunning is illegal, but there may be specific exemption for religious slaughter. In the European Union (EU), for example, Directive 93/119, Article 3 requires that no animal should be caused or permitted to sustain any avoidable excitement, **pain** or **suffering** during restraint, stunning, slaughter or killing. Directive 74/577, Article 2, provides for religious slaughter to be exempt from this requirement. However, there is no such exemption in certain European countries, including Sweden and Switzerland.

It has been argued, in a highly regarded scientific journal, that the behavioural responses of animals slaughtered using religious methods, as well as neurophysiological studies, suggest that these methods are painless and humane. Many other scientists strongly disagree with these conclusions. However, such methods would undoubtedly have been more humane than those likely to have been used previously, where more than a single cut was permitted and where there was no requirement for the operator to be proficient, for the knife to be razor sharp and free from blemishes or for all vessels supplying blood to the brain to be severed. Due to the difficulties in restraining animals in an appropriate position, throughput rates on religious slaughter lines may be slower than on conventional kill lines.

Fig. R.3. Arterial arrangement in the sheep (from Baldwin and Bell, 1963).

The principal welfare problems associated with religious slaughter are considered to be:

- **fear** and **distress** during restraint;
- severe pain and distress due to the throat being cut;
- distress resulting from inhalation of blood through the severed trachea;
- prolongation of pain and distress in cattle due to their unique pattern of blood supply to the brain, and thus a prolonged period of sensibility; and
- prolongation of fear and distress due to reduced rate of blood loss resulting from the neck folding and/or occlusion of arteries.

There is evidence that pre-slaughter restraint of animals in boxes designed for religious slaughter may cause higher levels of stress than conventional boxes and that the period of restraint may be prolonged. There is also evidence that manual inversion of sheep may be physically demanding and may lead to animals being lifted by the fleece.

The Farm Animal Welfare Council (**FAWC**) in the UK, in their report (FAWC, 2003), concluded that, during the transverse neck cut at slaughter there is massive injury to tissues, including skin, muscle, trachea, oesophagus, carotid artery, jugular vein and major nerves. They considered that this results in the conveyance of very high levels of painful sensory information to the brain of the conscious animal, causing significant pain and distress. This conclusion differs from that of other scientists, who conclude that the sharpness of the knife prevents stimulation of pain receptors.

During slaughter, blood from the severed blood vessels is inhaled through the cut end of the trachea, which enters the lungs causing further distress through an experience of asphyxiation, with associated choking reflexes.

The course of the vessels supplying blood to the brain, for sheep and for cattle, is presented diagrammatically in Figs R.3 and R.4. The principal supply for most species is via the two carotid arteries, which are located on the ventral, or lower, aspect of the neck, either side of the midline; the vertebral arteries do not join directly with the cerebral vessels. In cattle,

P.520

additionally, the two vertebral arteries, which run either side of the spinal column in the dorsal, or upper, neck, join directly with cerebral vessels and supply a significant proportion of blood directly to the brain. The vertebral arteries are not severed by the transverse ventral neck cut used in *shekita* and *halal* slaughter protocols, with the result that blood supply to the brain may be prolonged.

Fig. R.4. Arterial arrangement in the calf (from Baldwin and Bell, 1963).

Furthermore, the carotid arteries may be occluded following neck cut on occasions when the head slips free of the restraint and the neck folds. Occlusion may also result from the retraction of the connective tissue coat of the artery, and collapse of the elastic walls; blood may then collect in the connective tissue sealing the cut ends. This results in an increase in blood pressure in the vertebral artery, which therefore continues to supply the brain, thereby delaying insensibility. The practice by some religious slaughtermen, of placing a hand into the neck wound immediately after neck cut, in an attempt to prevent occlusion of the arteries due to elastic collapse of the walls of the carotid, causes additional pain and distress and may be ineffective. Supporters of religious slaughter argue that ballooning of vessels does not occur due to the sharpness of the knife but the FAWC found, during visits to observe religious slaughter, that ballooning did occur.

Scientific studies, using encephalography, show that the duration of consciousness after a knife cut may be up to 60 s in adult cattle, while in calves, consciousness has been shown to remain for up to 120 s, depending on the degree of occlusion of the blood vessels. Sheep and goats become insensible in less than 7 s. This contrasts with an immediate loss of consciousness that has been shown to occur following captive-bolt stunning.

A significant volume of meat from animals killed by religious methods is unsuitable for use as *halal* or *kosher* product due to religious considerations, but is otherwise fit for human consumption, including hindquarters, as religious texts require that they not be eaten unless certain blood vessels are removed. This meat may be sold on the open market, without being labelled as slaughtered by religious methods. This would be of some considerable ethical concern to non-Jewish and non-Muslim consumers, for whom animal welfare is an important aspect of meat quality, were they to be aware of this practice. The societal consensus in European countries, that pain and distress arising from slaughter without stunning is ethically unacceptable, has resulted in legislation being enacted to ensure that animals are stunned prior to killing. The FAWC in the UK has recently recommended that the exemption for religious slaughter of the legal requirement for pre-slaughter stunning, under the Welfare of Animals (Slaughter and Stunning) Regulations 1995, should be repealed. However, this recommendation was not accepted by the UK Government.

Repetitive behaviour

Behaviour is repetitive when the same behaviour pattern is repeated over a short period of time. Bouts of the repetitive behaviour may also be repeated. The behaviour is usually similar each time it is performed. It has been suggested that the performance of rhythmical, repetitive behaviours may have comforting properties (**see: Comfort behaviour**) and that it may become addictive, through the associated release of endogenous **opioids** (Cronin *et al.*, 1986). Examples of repetitive behaviour include normal adaptive behaviours such as ingestive behaviour of herbivores and blinking, as well as maladaptive **abnormal** behaviour patterns such as the **stereotypies** of **weaving**, **crib-biting** and **stall-walking** in horses.

Repetitive behaviours may be learned or variations of **instinctive behaviour** patterns, e.g. **vocalization**, chewing, walking, that are necessary for the survival or reproduction of the animal. Once developed, some repetitive behaviours may be

P.521

more easily elicited and become less dependent on external factors for their reinforcement or development. A repetitive behaviour may however be dependent upon the continued presence of a **stimulus**, for example food in the mouth stimulates chewing and swallowing until the mouth is empty. Other repetitive behaviours may be **reflexes** that have been conditioned by the association of a reward with the performance of the behaviour, e.g. attention-seeking spinning by a **dog**.

Some repetitive behaviours present as behaviour problems in animals, and so understanding the **aetiology** of a given case is important, and an assumption should not be made that all repetitive behaviour problems are stereotypies. For example, horses that repeatedly shake their heads may simply be responding normally to a stimulus that is repeatedly being presented (e.g. poorly fitting tack or biting insects). However, for some, the performance of the behaviour appears to be related to neuralgic pain and in others it may have become a **habit** or be a dysfunctional behaviour and become emancipated from the stimulus that originally elicited its performance. In these cases the bouts of repetitive behaviour may be quite sustained and the animal may appear to have difficulty ceasing it.

Just as the term 'stereotypy' is inappropriate for all of these behaviours, so is the term 'obsessive-compulsive disorder' or 'compulsive disorder', since these terms imply a common mechanistic basis. However, it has been suggested that when a repetitive behaviour appears **abnormal**, it may be more useful to refer to it as abnormal repetitive behaviour or stereotypic behaviour (with the term stereotypic used to convey that it is like a stereotypy, but it may not have the precise mechanistic basis of a stereotypy as implied in the human medical literature) until its precise mechanism is more clearly elucidated, when it can be more precisely labelled (see Fig. R.5). However, these conventions have yet to be widely adopted within the literature.

Reproduction

Reproduction refers to the propagation of a new individual, and may arise sexually or asexually. While sexual reproduction involving the fusing of gametes from different individuals is the norm in the animal kingdom, sexual reproduction by hermaphrodite individuals (in which a single individual produces both the eggs and sperm of a mating) and asexual reproduction also occur in both invertebrates and vertebrates. For example, the mangrove killifish (*Kryptolebias marmoratus*) has a mixed mating strategy, with hermaphrodites engaging in both self- and cross-fertilization, while the female hammerhead shark (*Sphyrna*) may reproduce asexually through parthenogenesis. Some species can alternate between sexual and asexual reproduction (heterogamy) according to the prevailing conditions, in order to capitalize on the advantages associated with each strategy. Sexual reproduction has the advantage of allowing genetic mixing through the fusion of gametes produced by meiosis (even in the case of intra-individual sexual reproduction). This can facilitate adaptation in a changing environment and may result in change in the gene frequency within the population. By contrast, asexual reproduction facilitates rapid colonization of new areas, and may be a particularly successful strategy in stable environments.

Reproductive behaviour

Reproductive behaviour is poorly defined as an entity and can be used to refer to all behaviour associated with successful reproduction or a subset of these that are more directly associated with mating. Thus it may refer to behaviours associated

behaviour - including brooding and **nursing** - **paternal behaviour** and other aspects of parental behaviour, as well as behaviours associated with maximizing reproductive opportunity such as **territoriality**.

(DSM)

See also: **Reproduction**

Reproductive suppression

Reproductive suppression may be defined broadly as inhibition of reproductive physiology and/or **reproductive behaviour** in an otherwise fertile individual in response to specific environmental or physiological conditions. By this definition, reproductive suppression involves disruption of normal reproductive processes by inhibitory influences, rather than simply the absence of stimulatory influences. Reproductive suppression has been documented in a broad range of taxa and occurs in both sexes. It may be triggered by a variety of factors from the internal and external environments, and may involve inhibition at a number of different stages of the reproductive process.

Reproduction can be highly risky and energetically demanding, especially for females. Moreover, the likelihood that any particular **breeding** attempt will succeed - that is, that it will produce surviving offspring - may depend upon prevailing conditions in the physical, biotic and social environment, as well as upon the potential breeder's physical and physiological condition. Thus, to the extent that current reproductive attempts decrease prospects for survival or future reproduction, individuals of many species may increase their lifetime reproductive success by timing their reproductive attempts to occur during favourable conditions and, correspondingly, curtailing their reproductive activity at other times. Natural **selection** may therefore be expected to favour those individuals that undergo reproductive suppression under inauspicious conditions.

Reproductive suppression can occur in response to variation in either physiological or environmental factors that are otherwise associated with, or predictive of, poor reproductive outcomes. Physiologically, the most important of these variables is energy balance. Reproduction in many (e.g. mammals) but not all (e.g. reptiles) taxa is suppressed when animals enter negative energy balance as a consequence of such factors as low food availability, high workload or activity levels, and low ambient temperature, or combinations of these factors. The metabolic signal(s) detected by the body and transduced into reproductive suppression are unknown. A critical role of body fat, once thought to be the key signal, has largely been discounted, and more recent attention has focused on potential roles of other metabolic fuels and metabolic hormones. In addition to energy balance, reproduction may be suppressed by such physiological states as **lactation** and illness.

The external environmental factors that influence reproductive outcomes can generally be categorized as dietary, physical or social in origin. In some cases, these same factors are used as proximate cues to trigger suppression (or activation) of reproduction. In other cases, animals respond more directly to factors that are not inherently crucial for reproduction but are predictive of critical changes in climatic or dietary conditions. For example, many species become reproductively quiescent on a seasonal basis, thereby avoiding breeding during periods of low food or water availability or adverse climatic conditions. The environmental cues that may be used to synchronize reproductive activity with seasonal changes in the environment are quite diverse, however, including such variables of direct reproductive significance as rainfall (e.g. zebra finch, *Taeniopygia guttata castanotis*), ambient temperature (e.g. green anole lizard, *Anolis carolinensis*) and food availability (e.g. Columbian ground squirrel, *Spermophilus columbianus*), as well as such predictive variables as **photoperiod** (e.g. sheep, *Ovis aries*) and availability of non-nutritive plant compounds (e.g. montane vole, *Microtus montanus*).

In many species, reproductive physiology and/or reproductive behaviour may be partly or completely suppressed by cues from the social environment. Social suppression of reproduction often involves agonistic or dominance-related interactions between same-sex adults. Among cooperatively breeding naked mole-rats (*Heterocephalus glaber*) and common marmoset monkeys (*Callithrix jacchus*), for example, behaviourally subordinate females typically exhibit low reproductive hormone levels and atrophied reproductive tracts, fail to ovulate and engage in little or no sexual behaviour while living with a dominant female, but commence normal reproductive function shortly after separation from the dominant female. In other species, **pheromones** may trigger reproductive suppression independently of direct behavioural interactions. For example, ovulatory or lactating rats (*Rattus norvegicus*), as well as female house mice (*Mus musculus*) living in large groups or dense populations, release chemosignals that extend or suppress oestrous cycles and reduce fertility in other females.

Reproductive suppression is less common and, usually, less pronounced in males than in females, presumably reflecting the lower costs of reproduction and/or higher maximum potential reproductive success in males. Suppression in males may involve either a delay in the initial onset of reproductive function or a subsequent inhibition of reproductive activity in mature, potentially fertile adults. Male orang-utans (*Pongo pygmaeus*), for example, may undergo a prolonged adolescent period, characterized by reduced levels of **androgens** and gonadotropic hormones, arrested development of secondary sexual characteristics and low attractiveness to females, if living in proximity to an adult male. In other species, fully mature, socially subordinate males may undergo inhibition of **sexual behaviour** (e.g. dwarf mongoose, *Helogale parvula*), impairment of spermatogenesis (e.g. naked mole-rat, *Heterocephalus glaber*) and/or suppression of androgen secretion (e.g. Alpine marmot, *Marmota marmota*).

Females have considerably more complex reproductive physiology than males and, not surprisingly, exhibit a greater variety of mechanisms by which reproduction can be suppressed. As in males, organismic or environmental factors may inhibit or delay maturation in young females or may reversibly impair reproductive function in otherwise fertile adults. Interactions with or cues from dominant females, for example, can delay puberty (e.g. Mongolian gerbil, *Meriones unguiculatus*), suppress ovulation (e.g. pine vole, *Microtus pinetorum*), inhibit sexual behaviour (e.g. rhesus macaque, *Macaca mulatta*), delay conception (e.g. yellow baboon, *Papio cynocephalus*), block implantation (e.g. white-footed mouse, *Peromyscus leucopus*), induce spontaneous abortion or prenatal

P.523

litter reduction (e.g. golden hamster, *Mesocricetus auratus*) or impair maternal care (e.g. ring-tailed lemur, *Lemur catta*) in subordinate females.

The environmental and organismic factors that determine poor reproductive outcomes may be considered **stressors**, and reproductive suppression is frequently assumed to be mediated by a **stress** response. Although reproduction can certainly be impaired by aspects of the stress response (e.g. elevated circulating concentrations of **glucocorticoids** or endogenous **opioids**), it is becoming increasingly clear that reproductive suppression frequently occurs in the absence of generalized stress and may instead be mediated by more specialized neuroendocrine mechanisms. The final common pathway for many of these mechanisms may be disrupted hypothalamic secretion of **gonadotropin-releasing hormone**, leading to inhibited release of **gonadotropins** from the **pituitary gland** and, consequently, to impaired endocrine, gametogenic and/or ovulatory function in the **gonads**.

Reproductive suppression may have profound implications for **captive breeding** and **conservation** programmes. As a consequence of the reproductive system's sensitivity to environmental factors, a particular species may show contrasting reproductive patterns in captivity and in the field, or even in different captive or natural environments, and may fail to breed under non-natural conditions. Clearly, the success of breeding and conservation programmes may be critically dependent upon an understanding of the organismic, environmental and social influences on reproduction.

Reptile

Traditionally, reptiles are the class of vertebrates that include squamates (lizards, snakes and amphisbaenids), turtles, crocodilians and the two species of the tuatara (found only on a few islands in New Zealand). Current taxonomic practice argues that if all these animals are in a single class, Reptilia, then so are their descendants - dinosaurs and birds. Others argue that the traditional Reptilia is not a monophyletic group, and thus should be broken up with, perhaps, only lizards and snakes as 'true' reptiles. Staying with traditional views, reptiles are ectothermic amniotes comprising roughly 3000 snakes, 4500 lizards, 160 amphisbaenians, 300 turtles and 23 crocodilians.

Reproductively, reptiles have traits found in both birds (oviparity) and mammals (viviparity). Post-hatching/-natal parental care, long thought absent in reptiles, is now known to be both complex and lengthy in all crocodilians studied, absent in virtually all turtles and the tuatara and highly variable in lizards and snakes. In fact, in some lizards, cohorts of offspring live with their parents and younger siblings for some years. Many crocodilians not only guard their nests for many months, but aid in the hatching of their babies when they hear them vocalize in the nest and transport them, very gently, to water. Probably the largest group, lizards, presents the most extreme diversity in terms of size, diet, reproductive mode, age at maturity, diversity of sensory mechanisms, parental care, sociality, social organization and habitat use. All this diversity makes any generalizations on biology, behaviour or husbandry impossible. Thus, it is necessary to consult references that provide such basic information, and some starting points are cited below.

Recognizing this diversity is also important because reptiles are increasingly featured in conservation plans, maintained and bred in **captivity** and even reintroduced to former native habitat. Conversely, many reptiles have been introduced into environments where they can be serious pests and do biological harm. The brown tree snake (*Boiga irregularis*), introduced from New Guinea into Guam, is perhaps the most egregious example, but in Florida alone the following are just a few of the introduced species that may need control: green iguanas (*Iguana iguana*), Nile monitors (*Varanus niloticus*), brown anoles (*Anolis sagrei*) and Burmese pythons (*Python molurus*). In Japan and Europe, North American emydid turtles such as red-eared sliders (*Trachemys scripta elegans*) are disrupting native species. Studies of natural history of these animals in native habitats, as well as in captivity, are needed if effective controls can be instituted. Unlike some invasive large mammals, the secretive nature and high reproductive potential of introduced reptiles makes control through hunting and trapping impractical and inefficient.

On the other hand, some species, especially edible reptiles, are being ranched and becoming domesticated. Alligator, iguana and turtle farms are prominent in several countries. In addition, many species of lizards and snakes are being bred for the **pet** trade, with aberrant colour morphs being developed. Such captive breeding is altering the behaviour and morphology of reptiles through both deliberate and unconscious **selection (domestication)**, as well as through phenotypic plasticity.

The literature on captive reptile maintenance, **breeding** and rearing has greatly expanded since the late 1980s. There are extensive works on veterinary care and volumes on captive care of almost all major taxa. The most commonly maintained species have been the subjects of many reports, many developed and written by amateurs or professional breeders. Academic and **zoo** biologists have also contributed much. European and American herpetoculture magazines abound. These often contain useful hints as well as leads for suppliers of equipment, diets, food supplements, innovative caging and other supplies.

A misconception about reptiles, still widespread, is that their behaviour is relatively unaffected by their rearing conditions and environment. In other words, unlike birds and mammals, reptiles are often viewed as more 'hard-wired', learning little if at all, and are psychologically not affected by the nature of their environment. Thus, reptiles not on exhibit in zoos and laboratories are frequently reared in relatively sterile and non-stimulating environments. What is increasingly

recognized is that reptiles, being ectothermic and ecologically specialized, often have a very narrow range of environmental conditions in which they can thrive. Chief among these are temperature, humidity, appropriate ultraviolet lighting and dietary nutrients. Discrimination studies on the sensory abilities of reptiles have documented keen thermal, chemical, visual, tactile and even auditory perception. But all these vary markedly across reptilian groups.

While the view that the learning ability of reptiles is limited was challenged years ago, the extent of the abilities of reptiles and their need for appropriate environments for psychological and behavioural **well-being** is of even more recent concern and only beginning to be explored. Environmental enrichment has been shown to be beneficial in promoting health and

behavioural performance in turtles, snakes and lizards, and experimental studies are urgently needed. Some reptiles even **play** in the mammalian way.

These considerations are important in learning about the many members of the second largest vertebrate class. Reptiles possess many traits that make them useful in basic research as well as for exploring solutions to behavioural, medical, ecological and conservation issues important to their survival and the habitats in which they are often an integral part.

Rescue shelter

A rescue shelter is an establishment that provides protection and care for displaced animals, usually **companion animals** but sometimes **horses**, farm animals and wildlife, or is restricted to looking after specific groups or species such as **reptiles** or donkeys. Animals enter rescue shelters for various reasons, including: (i) being accidentally lost after escaping or straying; (ii) being deliberately abandoned; (iii) being handed in by their owner; or (iv) having been seized by an animal **welfare** inspector through relevant legal powers in cases of suspected cruelty or neglect. The most frequently cited reasons for companion animals being taken by their owners to a rescue shelter are behavioural and accommodation problems.

The first official rescue shelter was founded in London in 1861 and was known as 'The Home for Lost and Starving Dogs', subsequently to become the Battersea Dogs' Home. Although most are run without government support, rescue shelters have subsequently become one of the key elements of the protection of animal welfare in many communities. They have four main functions: (i) to provide for the direct **needs of animals** in their care, including the alleviation of immediate **suffering** through appropriate veterinary treatment or **euthanasia**; (ii) to provide for the long-term care of animals not immediately reunited with their owner or placed with a new owner; (iii) to seek to reunite accidentally displaced animals with their owners; and (iv) to attempt to find new places or homes for displaced animals (rehoming).

Rehoming of companion animals may be dependent upon successful **temperament** and **health** evaluation. Where animals are not considered suitable for rehoming they may be committed to long-term care within the shelter, transferred to another shelter or euthanized. Some shelters have a policy of providing lifetime care of displaced animals that have not been rehomed ('no-kill' shelters), and in some countries such a policy is supported by legislation, e.g. Italy. In other cases the emphasis is on providing short-term shelter to all displaced animals, with those animals that cannot be rehomed being euthanized.

Resource

Any substance or organism that is valuable for a given animal may be referred to as a resource. Typical examples of resources are food or mating partners, but the term may also refer to **enrichment** devices for captive animals. Access to resources is usually supposed to give some benefits for **individual fitness**, so the less available a resource is the more competition there may be to access/monopolize it.

(BM)

See also: Resource-holding potential

Resource-holding potential

Game theory models, when applied to animal contests, predicted that three main asymmetries will influence how animals fight and thus determine the winner: (i) prior ownership of the **resource**; (ii) the value that each contestant places on the resource; and (iii) the overall fighting ability of each contestant, originally called resource-holding power and later resource-holding potential (RHP). Prior ownership was viewed as an asymmetry that is uncorrelated with the expected pay-off and used as a convention to settle the contest with minimum costs. Resource value is correlated with the potential pay-off in terms of expected fitness gain from victory. The animal that places the higher value on the resource should have a higher motivation to win and thus: (i) be prepared to accept higher costs; and (ii) be more likely to win if both opponents have equal RHP.

RHP includes any feature that might influence the ability to win at a particular time and thus comprises intrinsic aspects

P.525

such as body size, weapon size, previous experience and physiological states such as energy reserves or lactic acid, which induces fatigue. In addition, extrinsic aspects such as position relative to that of the opponent may influence RHP; for example, male amphipods that hold females are much more successful than are males attempting to displace them. Body or weapon sizes are easily measured and thus, in empirical work, are the most frequently used estimates of RHP. All other things being equal, the contestant of greater RHP is expected to be the eventual winner and this has been shown for a wide range of organisms, particularly with respect to body size. However, there are different theoretical models that explain the process by which this occurs, and these have only recently been tested in an effective manner.

Early models, such as the asymmetric war of attrition, presumed that each individual would have information about its own abilities and gather information about those of the opponent. That is, opponents would engage in mutual RHP assessment and the animal perceiving it was the weaker one would quit immediately and avoid wasted costs of engaging in a contest that it would probably lose. This idea was developed in the 'sequential assessment model', in which it was presumed that contestants would engage in bouts of fighting, gathering increasingly accurate information, with the weaker animal quitting as soon as an inevitable lost cause was perceived. Typically, interactions would start with displays before escalating to more costly activities. These displays should not easily be faked, otherwise that trait would spread in the population and then offer no way of assessing RHP (see: **Honest signals**). Displays should thus correlate with true RHP, and this has been shown for vocal displays such as the croaks of toads, with large toads being able to produce calls of low auditory frequency, or red **deer** stags, which can only roar vigorously if in good condition. Visual displays may also demonstrate the size of the animal or the size of the weapons that it may possess, such as with claw-waving displays of crabs. For the most part these

displays are expected to provide honest information, but bluff, exaggeration or dishonesty have been shown, particularly in stomatopods, snapping shrimps and hermit crabs.

Alternative models of how RHP asymmetry determines the winner presume that contestants do not gather information about their opponent but, instead, the surrender decision is based on the accumulated costs of staying in the contest. The decision will be triggered once a threshold level of accumulated costs, that the contestant is willing to accept, has been crossed. Possible costs have been modelled in terms of time, as in the 'war of attrition without assessment' (WOA-WA), and energy as in the 'energetic war of attrition' (E-WOA). In the 'cumulative assessment model' (CAM), the costs can accrue as a result of the contestant's own agonistic activities, but they can also be influenced by the actions of the opponent. How each contestant competes is determined by its own changing state or RHP, even though the relative RHP may influence the costs per unit time of being in the fight. In these models the smaller of two contestants would typically surrender first, so these models clearly predict that RHP asymmetry determines the winner. However, animals will fight for a period and thus will always be prone to incur costs prior to quitting. Indeed, the WOA-WA and E-WOA predict that fight costs to the loser should equal the value of the resource to that animal.

In contrast, the sequential assessment model predicts that animals will fight only until the asymmetry in RHP becomes apparent, with minor adjustment for resource value but without incurring costs up to the resource value. Own size assessment (OSA) is thus an inferior strategy to mutual assessment (MA) because, in the former, contestants typically pay higher costs for the same outcome. However, MA may not be possible because some species may lack the ability to gather information about the opponent due to inadequate sensory acuity or experience, high costs of assessment or a lack of reliable cues. Even with escalated fighting, in which opponents inflict wounds and induce fatigue in each other, contestants may only have accurate information about their own state and may have relatively little information about the condition of their opponent.

A prediction of the MA model is a negative relationship between contest duration and the relative size of the opponents. This supposedly diagnostic finding for mutual RHP assessment has been found in numerous studies, but these rarely considered other models. However, it has been demonstrated that both OSA and MA models produce the same relationship. The models can, however, be distinguished by the relationship between the winner RHP and contest duration. For mutual assessment this is negative whereas for own size assessment it is weakly positive. Furthermore, with OSA there will be an increasing duration of contests with increasing size of size-matched opponents, but this is not predicted by MA models. Tests using these criteria have shown that species of chameleons, spiders, crabs and amphipods cannot gather information about opponents. Other studies, however, clearly show that both contestants gather information about the RHP of the opponent, as is seen by the calls of toads and roars of red deer. Thus, it is clear that RHP is a major determinant of contest outcome, but the manner by which that occurs may vary considerably between species.

Respondent conditioning

Also known as either Pavlovian or classical conditioning, respondent conditioning refers to a form of associative learning that is assessed by evaluating the animal's change in response to stimuli within the environment as a result of the association of these stimuli. In other words the range of stimuli to which the animal will respond is changed as a result of learning (contrast this with **instrumental conditioning**, in which a response changes in response to its performance). The

P.526

phenomenon was first studied and described by **Ivan Pavlov** (hence the alternative name). Typically, in respondent conditioning, an unconditional stimulus that elicits an '**innate**' or unconditional response is paired with a neutral **stimulus** that, prior to conditioning, does not trigger the response, in such a way that it eventually comes to trigger the response when not paired with the unconditional stimulus. It is then referred to as a conditioned stimulus (or conditional stimulus), and the response that it triggers a conditioned response (or conditional response). Careful behaviour assessment often reveals that the conditioned response is not identical in form to the unconditional response, and may contain greater **appetitive behaviour** elements.

Resting behaviour

Resting is a **comfort behaviour** that is important for health, in conserving energy and aiding both **thermoregulation** and maintenance of physiological efficiency. Many social species synchronize resting behaviour to reduce risk of **predation**. There may be competition for resting places, even if there is enough physical space for all animals to lie down, as some spots may be more comfortable or provide more protection from the elements or the **space** between them may be insufficient (**see: Flight zone**). This may lead to **agonistic behaviour** and monopolization of some spots by some animals. Some intensive production environments do not provide enough space for all animals to rest simultaneously, and thus behavioural synchronization may not be possible. This may also increase agonistic events and restlessness, leaving some individuals with less time to rest and **sleep** than others.

The ability to find space away from neighbours while resting may be important for thermoregulation. Different postures will also be performed in different amounts, depending on the amount of space available, with animals tending to spread out more or lie in a recumbent position when given more space. The optimum amount of resting time is not known for most species. As a result, the duration of resting behaviour is not a clear welfare indicator. If animals are stressed they tend to decrease resting behaviours and increase **vigilance**. However, animals that spend a lot of their time resting may be sick, diseased, in a depressed or anhedonic state and so have decreased **welfare**.

Restraint

Restraint is used to limit some or all of an animal's movement. In order to minimize injury to the animal and provide operator safety, restraint is used for transportation (**see: Transport**), examination, convalescence, surgery, **breeding** and handling of animals. The type of restraint used can depend on the animals' anatomy, physiology, behaviour, **temperament** and previous experiences. The procedure being conducted, location and available facilities can also influence the restraint method, as can the experience of the restrainer and the risk to the safety of the animal and persons involved.

Various restraint techniques have been developed, ranging from those that allow the animal relative freedom of movement within a confined area to those severely restricting or even stopping all movement. One of the most basic restraint techniques is psychological restraint. Psychological restraint involves counteracting or incorporating an animal's own behaviour, such as its flight distance (**see: Flight zone**), into its restraint. A skilled restrainer can approach an animal to the edge of its flight zone and observe it without that animal attempting to escape. Animals can also be trained to perform various acts or allow certain procedures to be carried out without the use of any means of physical, mechanical or chemical restraint. For example, chimpanzees involved in biomedical research can be trained to present their arm and hold it steady while receiving an injection.

Restraint can be achieved in some instances by diminishing certain sensory perceptions of the animal, such as by blindfolding it or placing it in a darkened room. Darkness can have a strong calming effect on animals, although placing a nocturnal species into a darkened room may be counter-productive. Restraint can also be achieved by stimulating particular senses, as can happen when particular body areas of some animals are stroked in the appropriate direction. Horses, for example, are particularly responsive to stroking and massaging above the shoulder (withers). Cooling can be used to reduce the ability of ectothermic species to respond to handling (thermal restraint); however, prolonged cooling can be deleterious to their health.

Trained, experienced personnel can use their hands, and sometimes other body parts, as a physical restraint tool. For example, a traditional method for restraining sheep being sheared involves the sheep being held slightly off vertical with its back being cradled by the shearer's legs and its inside front leg placed under the shearer's rib cage. Gloves can be used to protect the hands during restraint; however, these tend to be cumbersome and reduce the restrainer's ability to determine how tightly they are grasping the animal.

An alternative to using the hands or other body parts is usage of hand-held devices such as ropes, nets, snares and tongs. Such devices have proved particularly useful for restraining, or at least applying an initial hold, on free-ranging wild animals (**see also: Free-range animals**). One such example of hand-held restraint used primarily on horses is the twitch. The twitch, consisting of a loop of rope or chain on a pole, is slipped over the horse's upper lip and twisted, applying pressure and presumably **pain**. The pain sensed when the twitch is first applied leads to the release of opiates, which sedate the horse.

Confinement is a restraint technique often associated with livestock production, research laboratories and **zoos**. Animals are typically confined to a specific area such as a cage, crush, raceway or stockyard. Mobile barriers, such as sheets of perspex or plywood, are also used further to confine an animal to a particular area. Close confinement can be achieved mechanically by using apparatus such as squeeze cages or squeeze chutes. These devices are essentially a solid, bar-sided or mesh-sided box designed and constructed to hold one animal. Slings are another close confinement device and can be used to restrain certain animals for an extended period. Close confinement of some mammals, birds and reptiles can be achieved using special bags or by wrapping them in a towel. Adjustable plastic tubes are another alternative for some reptiles

P.527

and small mammals. Complete restraint of some species, such as birds, snakes and primates, can be achieved with a restraint board. Typically under sedation, the animal is fastened with tape or Velcro straps to a board. Another technique used completely to confine laboratory primates is the restraint chair; animals are fastened to the chair with neck, waist and limb restraints.

By placing animals into specific positions, some forms of physical and mechanical restraint can keep animals relatively still and, in some species, induce a lowered state of awareness. Rabbits, for example, appear to enter a torpid state if placed on their back and held for a short period. An important consideration when applying physical or mechanical restraint is the amount of pressure applied. Animals will struggle if insufficient pressure is applied, while excessive pressure causes pain or discomfort.

Drugs, such as diazepam and ketamine, have revolutionized the practice of animal restraint. Many species of animals that were previously difficult to restrain using other techniques, or requiring a major manipulative procedure, can now be handled with less stress and trauma using chemical restraint. Chemical restraints, used to sedate, immobilize or anaesthetize, can be administered either orally or injected, with immobilization typically occurring after 2-20 min. Chemical restraints can be used to restrain animals briefly or for several hours.

Electroimmobilization, involving a mild electric current passing through the animal's body, has been used to restrain some species by tetanizing their muscles with electricity. However, this procedure has been shown to be aversive to the animal and has no analgesic or anaesthetic effect.

Restraint techniques vary in aversiveness, with most causing some stress to the animal. When using any means of restraint, it is necessary to weigh the benefits of a controlled animal against the distress it causes the animal.

(MKP)

Retroduction

Retroductive inference was described by the 19th-century American philosopher and logician C.S. Peirce, who spoke of a kind of inference to explanatory hypotheses that humans share with the problem-solving abilities of many other animals. It differs from concepts of deductive and inductive inference focusing on inferences which take place when humans and other animals respond to anomalies. Deductive inference, argued Peirce, cannot yield new facts or truth (and is inapplicable to models of animal thought processes) and involves a generalization that must reach beyond the supporting evidence of its premises. Animal trainers are familiar with the difficulties animals face when attempting to generalize a sequence of actions. Retroductive inference, however, draws from perceived certainties to the solution of a problem.

For example, a dog displays signs of burning and blistering around the lips and in the mouth, accompanied by abdominal pain, vomiting and diarrhoea. A veterinary surgeon may reason from these clinical signs to a plausible hypothesis regarding the intake of a toxic substance. This hypothesis, if true, would explain the physical signs, and is consequently worthy of further investigation, even if on detailed examination the condition was caused by something other than poisoning. But in another culture, in another period in time, it might be plausible to infer that the dog had been bewitched. This inference is not merely unacceptable to anyone educated in a Western scientific tradition, it would not even arise.

Retroductive inference is selective with regard to the generation of hypotheses, whereby certain wild hypotheses - such as witchcraft - are restricted. On the other hand, some certainties enjoy the protection of the relevant community. Retroduction may involve a search through a hierarchy of hypotheses to find the most plausible, while at the same time limiting the scope of potential solutions to a problem. Accordingly, it is a valuable tool in the economy of research. Peirce spoke of special aptitudes for guessing correctly which ones humans share with other animals. Just as the chicken that successfully pecks its way out of the eggshell does not waste time on other activities, argued Peirce, so a scientist confronting a pressing problem cannot afford to waste time on endless hypotheses.

Although widespread in human thinking, retroductive inference - generating and selecting the most plausible solutions - can be observed in many forms of animal behaviour involving defensive strategies, tool making and predatory and reproductive activities.

Rhinoceros

Rhinoceros, along with their relatives the horses, are members of the order Perissodactyla. There are five extant species of rhinoceros: black (*Diceros bicornis*), white (*Ceratotherium simum*), Javan (*Rhinoceros sondaicus*), Sumatran (*Dicerorhinus sumatrensis*) and Asian greater one-horned or 'Indian' (*Rhinoceros unicornis*). Two species, the black and the white rhinoceros, are endemic to Africa, with the remaining three residing in Asia. Second to the elephant, rhinoceros are the largest terrestrial mammals and are included in the heterogeneous group of animals referred to as megaherbivores. White rhinos, the largest rhino, can weigh over 2300 kg, while the Sumatran rhino does not exceed 800 kg in weight. The black, white and Sumatran species have two horns, whereas the Javan and Indian have only one. After a gestation period of 15-17 months, females give birth to a single calf, weighing 40-60 kg depending on species. Females generally mature at age 5-6 and males at 7-8 years of age.

Scientific studies are beginning to document the behaviour and **ecology** of the two African species and the Indian rhinoceros, but little is known about the Sumatran and Javan species. Javan rhino are the least numerous and are rarely seen in the dense tropical jungles of Vietnam and Indonesia, where they are found. The primary means of monitoring this species is by installing 'camera traps' to document their presence. By contrast, the use of radiotelemetry to track and study white and black rhino in the more open habitats where they reside has led to a much better understanding and improved conservation management of these species, especially the white rhino.

All rhino species are strictly herbivorous, but possess different foraging strategies reflecting the preferred habitat in

which they are found. White rhinos occupy grassland habitat and have wide lips adapted for grazing on grass. In contrast, while sympatric with white rhinos, black rhinos prefer thick, bushy habitat (such as the bushveldt of southern Africa) and have narrow, prehensile lips for browsing on leaves and branches, including acacia trees with 5 cm thorns. The Javan and Sumatran rhinos are also primarily browsers. The Indian rhino is a grazer, feeding on grasses in lush alluvial floodplains. Rarely far from water, the Indian rhino is the most amphibious rhino.

All rhino species are relatively solitary, although some - especially white rhinos - can be found in small groups. Most social groups are short-term aggregations, but adult white rhinoceros females will form stable and enduring associations with subadults or, on occasion, other adult females. However, most rhino **social behaviour** occurs between mother and offspring and short-lived consort relations between males and females. Female rhinos have long inter-birth intervals - generally 2-4 years - and invest heavily in their offspring. Studies show that white rhino mothers in good condition invest more in male than in female calves. This finding is predicted by evolutionary models of **parental investment**. In polygynous species competitive males can produce many more offspring than females, but poor-quality males may have reproductive success much lower than the average female. Thus, mothers in good condition can maximize **fitness** by producing high-quality sons (when resources allow) that will fare better in reproductive competition.

Male-male competition for access to females, whether through territoriality or direct fighting in the presence of an oestrous female, can be fierce. Male white rhinos are highly territorial and maintain well-defined boundaries. They exclude other males, but may allow a submissive bull to share their territory. These beta-bulls typically do not breed and do not display dominant behaviour, such as urine spraying and dung-scraping. Although less well studied, black and Indian males appear to be less territorial. Courtship behaviour can include significant aggression between the male and female, especially among Indian rhinos. Females are not territorial and have substantial home range overlap with other females as well as with males. White rhino females' ranges are large and encompass several male territories. Because of their preference for grassland habitat, males defending territories with more grassland have more opportunities for mating. Females may select mates by remaining on the territory of a preferred male during their fertile period.

As relatively solitary species, the lack of direct contact limits most forms of **communication**. Rhinos use a number of **vocalizations**, mostly during brief aggressive or sexual encounters, but rely on olfactory signals for day-to-day communication. A great deal of information is transmitted in communal dung-heaps, which function like a community bulletin board. Rhinos visit dung-heaps, investigate the dung left by other rhinos and deposit their own dung. From sniffing dung they can determine the sex, age, reproductive condition, dominance status and the age of the dung.

All rhinoceros species are dependent on **conservation** measures and all but one are classified as **endangered** or **critically endangered** by the International Union for the Conservation of Nature (IUCN). Only the white rhino has moved up the list to 'near threatened'. Unlike most endangered species, many rhinos still have sufficient habitat to survive and, in some cases, thrive. Poaching is by far the primary threat to rhinoceroses. Their horns are valued in the Middle East, where they are used as dagger handles, and in China, where the horn is believed to have medicinal properties as a fever reducer. These markets create incredible demand for rhino horn, and locals can earn more than a year's income by slaughtering one rhino. Although the northern subspecies of white rhino is almost extinct, the southern white rhino is one of the great conservation success stories, coming back from about 20 individuals 100 years ago to more than 12,000 today. This remarkable turnaround can be attributed to the political willpower in several southern African countries, particularly South Africa, in establishing secure reserves and anti-poaching patrols. The Indian and black rhinos are also possible success stories in the making, both with growing but precarious populations. The Javan and Sumatran rhinos are critically endangered, with numbers so low - and still declining - that they are at immediate risk of **extinction**. The northern subspecies of white rhinoceros numbers only a few individuals and will probably become extinct in the near future.

Followed by anti-poaching measures and habitat protection, **translocation** is the most important conservation measure for white, black and Indian rhino. This strategy entails removals of surplus rhino from reserves with growing populations to repopulate protected areas where rhinos are rare or have been extirpated. This action has been highly effective for southern white rhino, once confined to a single reserve but now widespread throughout southern Africa. In the past decade translocations have figured prominently in expanding the geographic range of black rhino populations. While this programme is successful, the **temperament** of black rhino poses challenges to successful translocation. Stress following translocation can be debilitating, and panicked rhino can run into fences and sustain injuries. In the unstable social environment created by translocation, black rhinos often fight and even kill one another. Behavioural research is addressing ways to mitigate these problems by managing the post-release environment. Releasing many rhino at once can put all rhinos on an equal footing and reduce attacks by residents on newcomers. Dispersal and territory establishment can be managed by 'seeding' an area with rhino dung, as black rhinos prefer to settle adjacent to areas where these olfactory signals

indicate prior occupancy by other rhinos (called **conspecific attraction**). Aggression is also mitigated by releasing rhinos into larger reserves at lower rhino densities, giving the rhinos better opportunities to avoid direct encounters with unfamiliar conspecifics. A key finding is that black rhino **aggression** is related to lack of familiarity and, although solitary by nature, once social relationships are established aggression is less common.

Four of the five species of rhino are maintained in captivity. More than 75% of captive Sumatran rhinos died before reproducing and only one pair has produced offspring, making the successful establishment of a viable population unlikely. Captive black rhino populations are marginally self-sustaining and appear to be limited mostly by disease and nutrition issues. White rhinos are also marginally self-sustaining, but demographically are headed for a population crash because most breeders are **ageing** females. Captive white rhinos have been

P.529

the subject of more behavioural research because reproduction is compromised by enigmatic breeding problems. Many of the founding population (F_0 generation), given appropriate husbandry and management, reproduced well, but reproduction among captive-born (F_1) females has been extremely sluggish. Behavioural studies demonstrated that F_1 females show normal signs of behavioral oestrus and reproductive behaviour and that males are just as interested in courting and mating F_1 females. The prevailing hypothesis espoused by managers - that mothers or the older F_0 females behaviourally or physiologically suppress reproduction in younger F_1 females - has been contradicted by behavioural and reproductive data. Research indicates that the problem arises during the development of female calves in captivity, not as adults. Several researchers still actively pursue this intractable problem, now focusing on the developmental period. This research programme provides an example for how using behavioural research to test hypotheses can be directly applied to management of conservation breeding programmes.

Risk factor

A factor that increases the chance within a population of a particular condition occurring. Risk factors may be causal or non-causal (e.g. associated with the occurrence of the condition but do not contribute to its development). Potential risk factors for a particular condition can be identified by comparing the incidence of the factors between similar populations of affected and non-affected individuals. Risk factors can include genetically determined tendencies or (lack of) previous exposure to environmental factors including diet, pathogens or social interactions during key points in the individual's life.

Ritualization

This is the evolutionary process through which a behaviour becomes highly stereotyped with limited inter-individual variation. Ritualization is usually observed in behaviours having a communicative function and where the **signal** has to be unequivocally interpreted by the receiver. Aggressive and submissive displays are typical examples of ritualized behaviour.

Robotic milking

Robotic milking is a type of automated milking system that is available for dairy cows. The cows present themselves at a gate when they are ready to be milked, where their individual electronic tags are recorded. The cows are then allowed access to the milking parlour where a robot cleans the udder and attaches the milking cluster, based on individual cow data stored in the computer and using proximity sensors, while the cow is fed a grain ration. There are a number of advantages to this type of system, as the computer records daily milk yield, allows detection of **disease** - such as **mastitis** - and compares these data with past records to determine any variation from an individual's expected values. In addition, the cows are given more control over their behaviour and can choose when and how often they are milked, and there is no need to dock the cows' tails (see: **Docking - tail**) in this system.

(LMD)

Rodent

Rodents are the commonest and most diverse of mammals, comprising about 40% of all mammalian species. Their name is derived from the Latin *rodere*, meaning 'to gnaw'. These animals are seen more as pests in most countries in that they compete for the same food as humans (it has been calculated that they eat 42.5 million t of food each year, i.e. 5-10% of total production). They are important vectors of **disease** and it is said that they have killed more humans than all wars put together. On the other hand, they have contributed enormously to our understanding and treatment of various diseases in humans. They are also increasingly kept as **pets**. Rodents are defined by a continually growing (several millimetres a week) pair of incisors on upper and lower jaws, which differentially wear, ensuring a sharp edge to the teeth. Their well-developed head muscles enable them to crack open various seeds to obtain food, as well as to gnaw through relatively hard materials such as wood and even concrete. They tend to be highly social animals, live in large groups with a **hierarchy** and are able to reproduce rapidly and in large numbers (the young develop to sexual maturity early and they have relatively short gestation periods).

Rollin, Bernard

Bernard Rollin (b. 1943), Professor of Philosophy, Physiology and Bioethics at Colorado State University, USA, has helped to expose and call into question the underlying values in animal and veterinary science, respectively. Rollin has written extensively on animal ethics, animal biotechnology, veterinary ethics, animal agriculture and genetic engineering. His (1995a) contemporary animal *husbandry ethic* attempts to foster a new consensus animal ethics by offering alternative solutions that focus on meeting the evolutionarily inherited adaptations of farmed animals. Rollin's ethic incorporates elements of interspecific equity, human virtues of restraint and diligence and animal **welfare** science. Rollin rejects the 'one-size-fits-all' application of a single moral principle (like the principle of

utility) to the animals' issue and opts to rejuvenate a mutually advantageous social contract with animals.

In animal agriculture and biomedical research, we should revisit the tenets of good husbandry practices grounded in an 'interspecific contract' that binds us to certain commonly accepted obligations for resource animals under our charge. The

social ethic regarding animals demands that those that benefit from animal production and use, provide animals with proper care and **housing** and management practices, be solidly grounded in an appreciation of the animals' points of view.

Presently, the industrialized paradigm of animal use has left this contract in a state of disequilibrium: lopsided in favour of human interests at the cost of genuine commitment to animal welfare. Producers and agribusinesses, for example, can today employ technologies that undercut practices that once underscored the contract: 'If one's animals did not fare well, then you did not either'. While not intentionally perpetuating cruelty to animals, the aim of efficiency and abundance of cheap food under the industrial paradigm have, through the deployment of technological fixes and layers of agribusiness, masked the tenets of a mutually advantageous relationship. The industrial paradigm has shifted focus from standards and values commensurate with the status of animals as biological and biographical beings to the terminus state of commodities.

Rollin's critique reflects to two major philosophical underpinnings, namely, the notions of **telos** or 'natural' or 'intended' lives, and the principle of welfare conservation. In the first instance, Rollin appropriates the Aristotelian notion of telos as an heuristic device to articulate the content of our duties towards animals. For Aristotle, telos or 'end' captures the 'purpose' and hence, 'good' of the being in question. The telos of a living being, for example, is to live what amounts to a life that is suited for things of that kind. For humans, our species is constituted towards a life suited for rationality and sociability.

A good life for any specific animal is one in which everything is functioning as evolution has adapted it to function. Telos is 'a nature, a function, a set of activities intrinsic to [an individual of a particular species], evolutionarily determined and genetically imprinted'. From our ordinary phenomenal experiences of animals, we know that '[they] have natures - the pigness of the pig, the cowness of the cow, "fish gotta swim, birds gotta fly" - which are essential to their well-being. Common sense tells us that animals that are built to move need to move to feel good; there is no point in trying to prove that they are fine if kept immobile.' Hence, '[t]o promote welfare of animals, we need to raise them in ways that respect their natures' (Rollin, 1995a).

These telic ends impose ethical limits on our treatment of animals and prescribe responsibilities as part of a fair exchange: 'use for care'. The peculiar species constitution of individual animals serves as a window to the functional needs of animals and reflects how animals can be harmed or benefited if their living conditions do not 'jive with their natures'. Animals fare well to the extent that they are exercising their natural capacities unencumbered, and they fail to do so when their lives do not accord with how they are designed.

According to Rollin, under today's industrialized conditions of raising and using animals, animals no longer live in a manner that corresponds to their adaptations and repertoire of natural behaviours. Animals do not have the requisite adaptations to meet the challenges of their human-made abodes. These conditions parallel 'putting round pegs into square holes'. What is needed is a concerted, system-wide effort to reshape housing systems and management practices to accord with certain optimal conditions for which animals are adapted.

The idea of central species defining properties is closely related to the principle of welfare conservation (Rollin, 1995b). This principle reflects his view of the morality of genetically modifying agricultural animals in order to fit their environments. Genetic alteration is wrong if it would worsen an animal's well-being in relation to **conspecifics** that do not receive the treatment or if it would have had a better life without the intervention.

In earlier works, Rollin uses the language of interests and rights. Rollin understands rights less stringently than strong animal rights proponent **Tom Regan** (Rollin, 1989, 1992). Deploying the language of rights (broadly construed) has utility, because as a tactic it affords protections to animals that ought not be subordinated to the general good. Rollin holds that while it may be acceptable to change the natures of animals through genetic means if doing so will on balance promote its welfare, it would be wrong to intervene in the human genome this way. Adding Nussbaum's capabilities view and Thompson's agrarian ideal view are nice departure points to Rollin's telic and husbandry ethic views, respectively.

Romanes, George J.

George J. Romanes (1848-1894) was perhaps the closest academic colleague of **Charles Darwin**, and is now best known for his interest in comparative psychology, although he was originally recognized scientifically for his work on the nervous system of invertebrates. He used anecdotal case studies to support his suppositions on the mental ability of non-human animals, and while some argue that there is much **anthropomorphism** in his work, others highlight the rigour with which he investigated cases and his attempt to frame them within an evolutionary context.

It is suggested that Lloyd Morgan formulated his canon (see: **Morgan's Canon**) in direct response to the publications of Romanes. Romanes was not a poor-quality scientist, as suggested by some of his critics, but was critical of Darwinian natural **selection** as originally proposed, highlighting several problems with the concept, and coined the term 'neo-Darwinism' to distinguish his refinements. This term has since been adopted by biologists to describe current views of evolutionary theory, which go beyond the original refinements proposed. Of particular significance was his insight into the

P.531

importance of selection working at the level of reproductive performance and the necessary reproductive **isolation** required for speciation to occur in many contexts.

Roosting

At night, many birds **sleep** either standing or, more usually, in a sitting position, perching on tree branches - a behaviour known as roosting. Birds usually seek out places to roost well before dark, even in short winter days, and the cue to go to roost has been shown to be the light dropping below a certain intensity.

Many species of bird have preferred roosting sites within a **home range** to which group members move at night. It is likely that there has been strong **selection** for roosting behaviour, as birds that choose to rest at night in elevated locations run a significantly reduced risk from predators. In addition, by roosting together, birds may benefit from conservation of heat. The formation of large roosting sites in urban areas can pose a serious environmental problem. Starlings sometimes flock into cities, and up to a million birds may assemble at a roosting site, producing huge quantities of droppings. In addition to the **health** and noise problems this may cause, it can result in damage to the structures upon which they roost by the weight of the birds and their droppings, as well as through damage from chemicals in the droppings.

Chicks must learn to roost when young. Junglefowl and feral hens will roost on the ground with their chicks until they are about 6 weeks of age, at which time the hen will begin to take chicks on to lower branches at night for roosting, encouraging them to fly up with a 'roosting call'.

Roosting appears to be a strongly motivated behaviour in domestic fowl. When perches are absent or inaccessible, birds will display signs of unrest, probably due to **frustration** or **exploratory behaviour** as they search for an alternative site to roost. In commercial systems, in which perches are provided, the majority of hens will use perches to roost at night, with most on the highest perches available. It is likely that hens housed in conditions that lack a perch to roost on experience reduced

welfare due to reduced **bone strength** and inability to avoid pecking by **conspecifics**, as well as frustration to perform the behaviour itself.

(RJNM)

Route tracing

Route tracing involves the relatively invariant following of a track within an enclosure. In addition, the repetitive and apparently functionless characteristics of route tracing mark it out as a stereotypy. Recognized in incarcerated humans, route tracing may reflect an individual's **behavioural need** to move within its habitat even though it may have been provided with key resources for survival. Such movement for its own sake may be driven by the need to explore and locate fresh resources. The prevalence of this response in isolated animals is strongly suggestive of the value placed on contact with **conspecifics** and the deleterious effect isolation can have on the welfare of both domestic and **captive animals**, especially social species.

Repetitively pacing animals in enclosures often cause concern among lay people, who most often label this and other locomotory stereotypic behaviours as a sign of boredom. The problem with the term boredom lies in its tendency to evoke human mental states that relate to a lack of cognitive challenge. A more conservative approach is to diagnose animals that begin to show stereotypic behaviours as being subject to thwarted **motivation** and then to identify the motivation that is being thwarted. To do so, applied ethologists may add substrates and reinforcers to measure their effect on the tendency to stereotype.

Although it is sometimes seen as a means of filling vacuum periods, route tracing can affect **welfare** by reducing the time available for maintenance behaviours, such as eating and resting. Additional effects on animal welfare relate to asymmetrical wear and tear, e.g. of pads. Blocking the path with obstacles and distracters is virtually fruitless as a management response, but radical changes in the enclosure and the institution of a new **time budget** may disturb the pattern shown and the frequency of stereotypic episodes. There is current debate as to whether the incomplete disappearance of the stereotypy constitutes evidence for so-called **emancipation** (the liberation of stereotypic behaviours from their initiating causes). On one hand it is argued that the resistance of route tracing to change means that the behaviour can become less relevant to the animal's immediate needs than it was when it first emerged. On the other hand, the (albeit incompletely) reduced frequency and intensity of the stereotypy in environments that have been, however transiently, enriched is seen as an indication that its function has become less critical.

R-R interval

The R-R interval, alternatively referred to as the inter-beat interval, normal-to-normal interval or heart period, can be defined as the time difference (in ms) between two successive R waves in a **electrocardiogram** QRS complex. Although any two points in adjacent cycles may be used to calculate the interval, the R-R interval is most commonly reported.

(RM-F)

RSPCA and Inspectorate

The Royal Society for the Prevention of Cruelty to Animals, now generally known as the RSPCA, was founded in England in 1824. Its formation followed the development in the early 1800s of the humanist movement, which advocated the protection of certain basic rights for the most vulnerable in society. From this arose the first animal welfare legislation, presented to the British House of Commons by Richard Martin MP and passed in 1822. This bill acted 'to prevent the cruel and improper treatment of any horse, cow, ox, heifer, steer, sheep or other cattle in the charge, care or custody of any person or persons'. It applied only to farm animals or beasts of burden. Further attempts were made by Martin to extend this legislation to **dogs**, **cats** and other animals, but these failed. It was some years before **animal cruelty** legislation was extended to cover the majority of vertebrate animals.

The RSPCA began with a meeting on 16 June 1824 in Old Slaughter's Coffee House in London. The meeting sought to form an organization 'instituted for the purpose of preventing

cruelty to animals' that would seek both to prosecute offenders under the new legislation, but also to 'alter the moral

feelings of the country' towards the welfare of animals. Twenty-two people attended the meeting, including the inaugural Secretary of the society, the Reverend Arthur Broome, Richard Martin MP and William Wilberforce MP, the anti-slavery campaigner. In 1835 the Duchess of Kent and Princess Victoria became patrons of the Society, and Victoria was active in her encouragement of the Society's activities. When Victoria became Queen she permitted the prefix 'Royal' to be assigned to the Society.

The RSPCA movement quickly spread internationally. In 1845, the French Soci  t   Protectrice des Animaux was formed. This was followed in 1866 by the formation in New York of the American Society for the Prevention of Cruelty to Animals. By 1869, the SPCA had also been founded in the states of Massachusetts, Pennsylvania, New Jersey, California, Illinois and Minnesota. Prevention of cruelty to animals laws, similar to those enacted in England, were introduced in each of these states. In 1877, the leading US societies met to form an alliance that became known as the American Humane Association. Similarly, SPCAs were also formed in Canada in 1869, in Australia in 1871 and in New Zealand in 1882. Those Societies based in Commonwealth countries individually gained the right to the use of the term 'Royal' and most are still referred to as 'the RSPCA'.

An integral part of the foundation of the RSPCA was prosecution of prevention of cruelty to animals legislation. At first this involved the formation of a committee inspecting markets, **slaughterhouses** and working horses in and around London. The Reverend Broome also used his own money to employ two men to carry out such inspections. In 1825, 63 offenders were brought before the courts. By the late 1830s an Inspectorate of five men had been established, based in London.

Then, as now, the Inspectorate worked both to prosecute animal welfare legislation and to educate the community about the laws regarding animal welfare. The UK RSPCA is the most well-resourced Society of the movement, with more than 320 RSPCA inspectors operating across England and Wales. The legal powers of RSPCA Inspectors vary, as they are dependent on the enabling legislation of the state, but they can include the right to enter property and seize animals where animal welfare has been compromised to the point of breaking the law. These rights can also be seen as limitations in terms of the possible actions of Inspectors. While RSPCA policies may not support practices such as the keeping of hens in battery cages, Inspectors cannot act to prevent these practices where they are legally permitted. Inspectors also perform a valuable role in educating individuals about the care and protection of animals and promoting the policies of the RSPCA.

The main objectives of the RSPCA today are fundamentally the same across the world and have changed little from the original intent of its founders: (i) to prevent cruelty to animals by enforcing existing legislation; (ii) to work towards improving such legislation for the protection of animals; (iii) to educate the community about the humane treatment of animals; and (iv) to encourage and sustain public debate on animal welfare.

The RSPCA works to improve animal welfare across the whole spectrum of human-animal interactions, including **farmed animals**, **companion animals**, animals used for sport or entertainment, **wild animals** and animals kept for research purposes. As well as its law enforcement role, the RSPCA's activities include the practical application of animal welfare, such as running **animal shelters**, clinics, hospitals and specialist wildlife centres, as well as high-profile campaigning, government lobbying and education. Market research consistently indicates that the name 'RSPCA' has an extremely high level of recognition and is well respected by the general public. While there is no formal affiliation between RSPCAs internationally, most have established connections and associations within their region and internationally to promote animal welfare and to work cooperatively on international issues.

In practice the RSPCA's work is limited to protecting the welfare of *sentient* animals. In most cases this will reflect the definition of animals contained in the organization's enabling legislation, which is generally restricted to vertebrates. More recently the RSPCA has argued for the inclusion of other species (e.g. cephalopods) where the level of neural development is such that pain perception has been demonstrated, or is likely to occur.

The original philosophy of the RSPCA movement reflected that of the first animal welfare legislation: that unnecessary cruelty to animals was unacceptable. The Society sought to improve the treatment of animals without challenging the inherent right of humans to use animals as sources of food, clothing, labour or entertainment. Since its foundation, the RSPCA and the general animal welfare movement that it inspired has continued to expand, improve and enforce animal welfare legislation around the world.

The RSPCA and like-minded animal welfare organizations continue to accept some use of animals by humans, provided that it is justified and humane. In contrast, many animal rights organizations advocate an end to the use of animals by humans altogether. Acceptance of the use of animals by humans is at the core of the difference between the RSPCA and the animal rights movement. This is made clear in their respective positions on the killing of animals for food. Many animal rights groups have a stated policy opposing the killing of animals for food. The RSPCA movement does not oppose this but has

worked progressively to improve standards for farm animals. In recent years this has extended to the establishment of **farm assurance schemes** that guarantee a high standard for the welfare of animals on accredited farms.

Rumination

A challenge facing many species of herbivorous mammal is how to access the nutrients contained within the cellulose cell walls of plant cells in the absence of the ability to produce a

P.533

cellulose enzyme. Rumination (colloquially referred to as chewing the cud) is the process used to maximize the digestibility of plant material by ruminants (i.e. animals with a multi-chambered stomach including a rumen). This includes species such as the cow, **sheep, goat, deer** and **camelids**. Typically these animals graze areas quite rapidly (**see: Feeding; Foraging behaviour; Grazing**) when the opportunity is presented, with herbage initially entering the large rumen. Later this material is repeatedly regurgitated, masticated and swallowed. As the material is broken down into smaller parts, and cell walls fragmented as a consequence, it is able more readily to leave the rumen and pass down the digestive tract for digestion to occur. Thus ruminants do not need to eat as frequently as some other herbivorous species such as **horses** (referred to as trickle feeders), and their feeding behaviour is interspersed with prolonged periods during which ingestion does not occur, but chewing behaviour is prevalent.

While rumination allows the release of nutrients high up in the digestive tract and so is very efficient when feeding on higher-quality forage, when faced with low-quality forage the rumen may become full of material of little value and the extraction of sufficient nutrients may be more difficult than in a trickle feeder. Also, if the gas associated with fermentation in the rumen is not released efficiently then the animal may develop the potentially fatal condition **bloat**.

(DSM)

Running wheel

Voluntary wheel running is one of the most widely reported behaviours performed by captive animals (Sherwin, 1998). In addition to pet and laboratory rodents, a wide range of animals will use running wheels, including hens, foxes, bobcats, domestic **cats, macaques, rabbits, ferrets**, dormice, flying squirrels, ground squirrels, bandicoots and Tasmanian devils. Wheel running can be a prodigious activity. In 24 h, the distance run can be as great as 43 km for rats, 31 km for wild mice, 19 km for lemmings, 17 km for the red fox and 16 km for laboratory mice.

It is a highly motivated, plastic behaviour, influenced by a wide variety of internal and external causal factors. It occurs spontaneously, usually within a few minutes or hours of access to a wheel becoming available. Some animals show preferences for square or triangular wheels (it has been calculated that mice running in square wheels jump at the corners at a rate of 15/s!), or wheels containing hurdles. Running wheels are generally preferred to other apparatus providing the opportunity for extended locomotion or exercise, e.g. treadmills.

There are several hypotheses regarding the function and causality of wheel running. One is that caged animals run in wheels as a means of regulating energy balance (Collier and Leshner, 1967). Another is that wheel running is motivated by information gathering, searching and exploration (Mather, 1981). A third suggests that wheel running is a self-reinforcing 'abnormal' behaviour that is a positive experience for the animal caused by feedback dysfunction, rather like humans enjoying a roller-coaster ride (Sherwin, 1998). It is sometimes suggested that wheel running is a stereotypy; however, the immediacy with which it occurs, the plasticity of its performance, its demonstrably high **motivation**, its performance in

complex environments and its various purported functions all indicate that it is not a stereotypy - at least not according to widely accepted definitions.

Runway test

This is a test used to measure the motivation to approach a reinforcing **stimulus (see: Reinforcement)**. The stimulus is usually a distinctively flavoured food presented to a food-deprived animal, usually a **rat** or **mouse**; other reinforcers may be presented, such as: water to a thirsty rat; access to intravenous injections of drugs of abuse; or access to a sexually receptive partner. The procedure has also been used to measure motivated behaviour in **pigs** and **fowl**. The apparatus typically comprises a start box, straight-alley runway and goal box. The animal is confined to the start box before the trial begins. At the beginning of a trial, the door of the start box is opened and the animal is free to move down the pathway into the goal box. The dependent measure is running time, which is the time from leaving the start box to entering the goal box. The acquisition of runway responding can be used to measure learning of an association between the reinforcing stimulus and the goal box (**see: Conditioning - types of**). This paradigm can also be used to measure aversive responding because reductions in reinforcement as well as omission of reinforcers have been shown to be aversive (**see: Aversion learning**).

Russell and Burch

Bill Russell and Rex Burch were commissioned in the mid-1950s by **UFAW** (the Universities Federation for Animal Welfare, Sir Peter Medawar) to write a book on minimizing animal **suffering** during experiments. It was eventually finished in 1959 under the title *The Principles of Humane Experimental Technique*. Within this text the concept of the **three Rs principle** (replacement, reduction and refinement) of laboratory practice was described, which has now been widely supported as an ethical obligation of research scientists. The three Rs also form a fundamental ethical framework and principle in legislation regulating research.

Ryder, Richard D.

Richard D. Ryder (b. 1940) is a British psychologist, writer and former chairman of the **RSPCA**.

The pejorative term '**speciesism**', which is employed by analogy with 'racism' and 'sexism' to deplore human beliefs and practices presupposing that *Homo sapiens* is morally superior to other animal species, is today associated with the philosopher **Peter Singer**. In fact, however, it was coined by Ryder, who, in his book *Victims of Science* (1975), says that he uses the word 'to describe the widespread discrimination that is practised by man against other species [...]. Speciesism and racism both overlook or underestimate the similarities between the discriminator and those discriminated against.'

It was in the early 1970s that Ryder became concerned about animal use in experimentation (he had himself undertaken animal experiments previously). At this time he contributed to the influential *Animals, Men and Morals: an Inquiry into the Maltreatment of Non-humans* (1972). It was in a widely noticed review of the former that Singer set out the anti-speciesist arguments he would later present in more detail in *Animal Liberation* (1975).

Despite their shared denunciation of speciesism, Singer and Ryder hold radically different views. Since 1985 Ryder has advocated a theory he calls 'painism'. In painism the central utilitarian idea that harms and benefits falling to several individuals can be added together, and that the morally right thing to do is whatever will bring about the greatest net benefit, is rejected. Troubled by the idea that large enough collective benefits can justify individual sacrifice, Ryder ascribes something like moral rights to each individual, human or animal. He also urges us to care especially about the plight of the 'maximum sufferer'. But, although he defends a prohibition on merely using others, including animals, for our own purposes, he sees his own position as one that steers a course between **utilitarianism** and the **animal rights** view (see: **Ethics**).

S

Sacred animals

Sacred animals are those offered some degree of veneration, respect or reverence. In many **cultures**, individual species or groups of animals may be given special ‘revered’ or ‘consecrated’ status, and this may affect not only the lives of the animals themselves, but also the lives of the people who interact with them, and the condition of the environment in which they live. Venerated status often derives from longstanding religious dictats; below are some examples of the religious views that different cultural groups have of animals:

- Buddhism: One of the five precepts of the *Dhammapada* - ‘he who destroys life - digs up the very roots of his life’.
- Hindu verse: He who kills a cow will ‘rot in hell for as many years as there are hairs on the cow’.
- Islam: ‘There is not an animal on earth, nor a flying creature on two wings, but they are people like unto you.’
- St Francis of Assisi: ‘Not to hurt our humble brethren is our first duty to them, but to stop there is not enough. We have a higher mission - to be of service to them whenever they require it.’

These dictats express deep intentions to respect and protect animals, but these aspirations are not necessarily achieved in practice. For example, to illustrate the **welfare** issues that veneration can cause, in Bali and Thailand long-tailed macaques are treated as sacred (*druwe*). In villages such as Ubud, Bukit Sari and Karangasem in Bali, thousands of macaques collect to be fed. These animals sometimes come into abrasive contact with man through damage to buildings and vehicles, by stealing and begging for food. Conversely, many monkeys are injured by vehicles, in fights with the dog population and as a result of fighting in competitive **groups** of monkeys in artificially tight groupings caused by the ready food source and lack of **predation** or control (see: **Social stress**).

These are not ‘natural’ behaviours, and the animals may become reliant on human supplies of food and lose natural foraging abilities. Wild monkeys from the forest of the Gumang Mountains, Bali, join these ‘temple groups’ to receive food from tourists - is their religious status adversely altering wild behaviours? If so, does this matter? These animals are very adaptable, and are simply using a new resource provided by man. Studies in American brown **bear** have shown that removal of feeding by tourists (and careful control of rubbish) eventually led the bears to leave tourist locations and to return to natural foraging - this reduced both the number of roadkilled bears and the number of dangerous interactions between the bears and man, and led to a more sustainable bear population. Local feeding of macaques may lead to unsustainable populations whose long-term welfare is threatened by complete dependence on human food and protection from predation.

In India, there are about 500,000 rhesus monkeys, of which nearly 60% live among humans. The monkeys have a consecrated status in Hinduism, where they are viewed as gods. Originating from the temples where they were sacred, monkeys have dispersed among the human population in a number of cities, from India to Indonesia. The rhesus monkeys, while sacred, are viewed by many as a problem because they move freely through and around public buildings, and are injured by cars, electrocuted in the tangles of electrical wiring on telegraph poles, defecate and urinate in buildings, may act as vectors for **disease** - including rabies - and fight with the local dog population.

In Hinduism, the cow is venerated. Verses of the *Rgveda* refer to the cow as Devi (goddess), identified with Aditi (mother of the gods) herself. Milk, curd, butter, **urine** and dung are used in rites of purification and penance. Cows are used to pull ploughs in the arid areas of India, but usually only buffalo or bullocks are used as **draught animals**. While protecting the cow from **slaughter** (except at the end of its ‘natural’ life), this veneration does not prevent some cattle from being subject to very hard living conditions on the street, or in very arid areas where feed is very poor - **starvation**, disease and neglect are still potential welfare threats to these animals, despite their being given religious status. The slaughter of milking cows is legal in only a few Indian states, so cattle may have to travel long distances by road for slaughter, and India exports large amounts of leather derived from cattle despite the cows’ sacred position. **Transport** of these cattle from state

to state subjects them to journeys that would be ‘unnecessary’ if slaughter was permitted locally - and it is the (sometime illogical) imposition of requirements such as these that, on a daily basis, affect the welfare of animals and do not provide any apparent immediate ‘benefit’ to man.

(AB)

Sacrifice

Sacrifice is the offering of something precious to a deity and, through history, living animals have been considered as ‘precious’ and suitable as offerings. Animals are universally killed for food, but the killing of animals as an ‘offering’ raises the possibility that lack of ‘control’ of the killing process, often carried out by priests or preachers, or by the public, can result in unusually long, or even artificially protracted, ‘time to **death**’, and the potential for significant suffering during the process of killing. Some examples of sacrifice still common in parts of the world include santeria, or *La Regla Lucumi*, which originated in West Africa, and is practised in many countries, but most commonly in Cuba, Haiti, Brazil, Trinidad, Puerto Rico and the USA. Sacrifices or offerings (*ebó*) of **chickens**, goats, doves and pigeons are used to mark significant events - the initiation of priests, births, deaths and marriages. The

P.536

animals are killed by decapitation, or by severing the blood vessels in the neck. This method of killing is very poorly controlled in comparison with the requirements for slaughter of farmed livestock.

In many parts of the world, sacrifices of **sheep, goats, buffalo, cattle** and birds are carried out to seek blessing for festivals, to atone gods or to mark visits by important guests. During the *Eid-El Kabir* festival, Muslims kill sheep and goats by public neck cutting. In countries where this is unlawful, local legislators have experienced difficulty in enforcing slaughter legislation in the face of claims that this interferes with religious rights. In Indian villages, animals are sacrificed to the gods Kali, Durga and Rudra to atone for sin. However, even within countries, different groups, religions and geographical areas have very different views on ritual slaughter, and this poses real difficulties for legislators who may wish to protect animals via national law, or via local orders, but find that inconsistencies from area to area make this complex.

The term ‘sacrifice’ may also be used within the context of killing during the process of **religious slaughter** for meat, and also as a euphemism for the killing of a subject as part of an experimental procedure.

Scent marking

Scent marking describes the release of chemical substances (e.g. **pheromones**) by an animal, for example by rubbing a specific gland on a surface, which acts as a signal for other animals. Scent marking is often used to signal territory ownership or to attract potential mating partners.

Seasonality

Seasonality refers to fluctuations in growth, development and reproduction seen with respect to changing seasons.

Photoperiod - i.e. the relative lengths of day and night - can reliably regulate seasonality because, unlike other 'seasonal' attributes such as temperature, rainfall and predominant weather patterns, photoperiod is consistent in its changing pattern over the course of a year.

From an evolutionary standpoint, it is therefore unsurprising that animals have used the predictability of changing day length to prepare for and optimize the timing of **reproduction**, migration and dormancy. The annual variation in day length between winter and summer will depend on latitude. Near the equator, variation is minimal; at the poles, variation is maximal. Within the polar circles at midsummer, there are 24 h of daylight and, at midwinter, there are 0 h of daylight.

A wide variety of animals from diverse taxa (for example, annelids, molluscs, arthropods, bony fish, frogs, turtles, lizards, birds and mammals) use the day length as an anticipatory cue to make seasonal preparations. From a biological fitness viewpoint, it is essential to reproduce at a time and place when food and environmental conditions will be best suited to successfully rearing the offspring.

Animals therefore may need to migrate, establish territory, build up fat reserves, moult, etc. to ensure fitness. The major controlling pathway of seasonality involves the pineal gland and its release of melatonin. Melatonin is released maximally during darkness and, as daylight increases, light **signals** received by the retina and transmitted to the pineal gland via the suprachiasmatic nucleus suppress melatonin synthesis. Melatonin then acts on the release of **gonadotropin-releasing hormone (GnRH)** and subsequently affects **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)** release, thereby exerting effects on reproductive function.

From an applied animal behaviour aspect, domestication of farm animal species, in particular, has sought to try to minimize the effects of seasonality. In the more intensive commercial livestock industries, the producer is aiming to control nutrition, photoperiod and thermal environment, so that there is little variation for the animal over the course of its life (**see also: Intensification of animal production**). For a breeding herd, the producer is trying to maintain continuous, predictable output in terms of number of offspring produced and subsequent growth rate. Eradication of seasonality has perhaps been best achieved in **pigs** and **cattle**. Feral pigs and cattle exhibit specific breeding seasons, with the aim of producing offspring from March through to June. Under commercial conditions, this seasonal breeding has all but disappeared, although there is evidence of reduced fertility if environmental conditions around the time of conception are suboptimal. **Sheep**, **goats** and **horses** continue to be seasonal breeders, but are most likely to be maintained in extensive farming systems.

Secure base hypothesis

The secure base hypothesis is derived from a development by Mary Ainsworth of John Bowlby's **attachment** theory.

Attachment theory proposes that the young of many species have a need for a reliable psychological relationship with a caregiver, who provides support and acts as a psychological buffer at times of **social stress**, and that this relationship has important influences on the future development of the young individual. It is suggested that the form of the attachment biases the emotional response and expectation of future close social relationships, and that this may account for a range of social disorders. Ainsworth developed a test, commonly

referred to as the Ainsworth Strange Situation Test (ASST), which sought experimentally to describe different types of attachment in young infants by subjecting them to a range of mild social **stressors**. The secure base hypothesis specifically proposes that the attachment characterized by a healthy 'secure base' facilitates exploration and response to challenges within the surrounding environment with more confidence. Some suggest that the 'secure base' also facilitates the development of a wider range of social cognitive abilities and skills.

The ASST has since been adapted for use in animals to evaluate the utility of the concept of attachment to describe the relationship between a **pet** and its owner. **Dogs** and **cats** appear to show some evidence of attachment behaviour in modifications of the test, but this is less evident in hand-reared wolves, suggesting that the capacity for attachment to humans may, in this species, be a product of **domestication**.

Selection

By Charles Darwin's (1859) own description, two pieces of information led him to the theory of natural selection:

1. The effects of selective breeding (artificial selection). Animal and plant breeders, even before Darwin's time, were aware that offspring tended to resemble their parents. Selecting only the parental stock with the best characteristics to breed in each generation led to steady improvements: maize with larger ears, fish with fancier fins, cows that produced more milk, and so on (**see also: Breeding**).
2. The 'struggle for existence'. This was a concept Darwin picked up from Thomas R. Malthus' (1798) *An Essay on the Principle of Population*. Malthus presented calculations showing that all species produce far more offspring than can possibly survive and reproduce. Individual females of some insect species, for example, produce hundreds of eggs in their lifetime. Obviously not all of the eggs of all of the females live to become egg-laying adults. Most species are more or less in a state of equilibrium. This means that, on average, each parent (in a sexual species) produces two surviving offspring. Malthus thought that population numbers were controlled primarily by competition for **resources**. (He predicted that the exponential population growth of humans would eventually be checked by starvation.)

Darwin's crucial insight was that, because not all organisms can live to reproduce, any trait that gives the individual bearing it an edge in the struggle to survive and reproduce would be more likely to be transmitted to future generations. This is natural selection. In artificial selection, the breeder, wittingly or unwittingly, allows only animals with particular traits to breed. Natural selection has the same effect, but through natural variation in survival and **reproduction**.

Selection in general can be defined as: 'nonrandom differential survival or reproduction of classes of phenotypically different entities' (Futuyma, 1998). This definition has several facets: 'differential survival or reproduction' means that not all individuals leave the same number of descendants; 'nonrandom' means there is some reason that some individuals do better than others; 'phenotypically different entities' means that there are measurable differences between individuals (the **phenotype** includes all characteristics of organisms except their genes). The reason this definition refers to 'entities' rather than individuals is that, theoretically, selection can also operate either below the level of the individual (at the level of genes) or above (at the level of groups, species or higher taxa). Selection is artificial when humans do the selecting; otherwise it is natural. Note that human activities also cause natural selection: selection for bacteria resistant to antibiotics is a good example. Selection leads to evolutionary change - that is, change across generations - only when the phenotypic differences are at least partly genetic; otherwise, it affects only the distribution of traits in the parental generation (**see also: Evolution**).

The classic example of natural selection in action: industrial melanism

Two centuries ago, before the Industrial Revolution, pale lichen covered the trunks of trees throughout the UK. Many insect species rested on these lichens during the day, protected by cryptic colour patterns closely resembling the colour of the lichens. (Cryptic means camouflaged, i.e. the opposite of conspicuous.) But lichens are sensitive to pollution, and were unable to survive on tree trunks near major industrial areas. In the late 1840s, the frequency of very dark (melanic) individuals began to increase in moth populations near big cities, where soot had killed the lichen and turned the tree trunks black. One species, the peppered moth (*Biston betularia*), went from about 1% melanic to over 90% melanic in less than 50 years.

In this species, the colour difference between light and dark morphs is controlled by a single gene. What caused the increase in dark forms probably was not the pollution itself but the effect that the colour change of the trees had on the crypsis of the moths. By pinning dead moths to trees, researchers showed that light moths were more likely to be eaten by birds when against dark backgrounds, and dark moths were more likely to be eaten against light backgrounds. They then released large numbers of marked moths in both polluted and unpolluted areas, and showed that light moths had higher survival in unpolluted areas and dark ones had higher survival in polluted areas. People watching from blinds observed that birds were more likely to eat moths that perched on the 'wrong' background, i.e. light moths that perched on dark trunks and dark moths that perched on light trunks. Today, in some parts of the UK, pollution has decreased, the lichens have made a comeback and so have the light-coloured moths.

This classic example illustrates several things. First, the researchers clearly detected selection - non-random differential survival of phenotypically different entities - and the colour trait is known to be genetically heritable. So this satisfies all the criteria for **evolution** by natural selection. We will never know with absolute certainty, however, whether

P.538

differential predation by birds caused the increased frequency of melanic morphs in the late 1800s. Second, because peppered moths have a 1-year life cycle, the dramatic change in morph frequency must have occurred in fewer than 50 generations. This is rapid for evolution by natural selection - it would be nothing, however, for artificial selection. By selectively breeding only dark moths, we could produce the same effect in a few generations. Finally, although the colour change was dramatic, on an evolutionary scale the change was quite minor. It did not result, for example, in the origin of new species.

Self-awareness and self-recognition

The study of self-awareness and self-recognition in animals is part of the wider field of animal **cognition**. A topic with many ramifications, it is of considerable interest in developmental, comparative and evolutionary **psychology**, cognitive science, the philosophy of mind, animal **welfare** and animal **ethics**. It is also inextricably tied up with the highly complex question of whether higher animals can recognize other animals as having minds, since self-awareness and other-awareness seem to be two sides of a single coin.

Following **Charles Darwin's** publication of *The Descent of Man* (1871), the idea that there is psychological continuity between animals and humans became a routine background assumption in much research on mentation in non-human species. Clearly, the assumption was supported by Darwinism. An argument from analogy also lent it credibility: where animals displayed behaviour in response to stimuli in ways similar to the way we do, it was reasonable to assume that they, like us, experienced mediating mental states.

However, an animal with self-awareness would not merely be aware of something that *happens to be* itself, as is the case when a cat cleans its paws. It would be aware of itself *as* itself. Self-awareness seems, therefore, to represent a step-change in psychological evolution.

Self-recognition - often equated with the ability to recognize oneself in a mirror (mirror self-recognition, MSR) - is a relatively primitive aspect of self-awareness. It emerges in humans around 18-24 months, with more abstract forms of self-awareness involving introspection and mental state attribution (**see: Theory of mind**) developing later. Even so, MSR is a highly sophisticated cognitive capacity and seems to be extremely rare in the animal kingdom: other than in humans it has been identified in our closest kin, the **great apes**; and lately it has been identified in a number of other species, including some dolphins and European magpies. This more recent discovery is of great interest, because dolphins, birds and primates differ so profoundly in their **brain** organization and evolutionary lineage.

Self-consciousness

Self-consciousness is the awareness of oneself as distinct from one's environment (**see: Self-awareness and self-recognition**). Sometimes, particularly in philosophical contexts, the term 'self-consciousness' is used to refer to various forms of awareness of oneself that are supposed to accompany conscious thought, sensation and other forms of experience.

In **René Descartes'** philosophy, it is argued that every conscious experience is connected with an infallible **knowledge** of oneself as an experiencing subject. Later philosophers have mainly been critical of Descartes' notion of self-consciousness. While some, like the Scottish philosopher David Hume, have wanted to jettison self-consciousness altogether, reducing it to a bundle of normal, object-related experiences, other philosophers, notably from the so-called phenomenological tradition in philosophy, have argued that a pre-reflective awareness of oneself is a precondition of any experience.

(PS)

Self-medication

The selection and consumption of substances that have little nutritional value but are either pharmacologically active or act in some form to improve symptoms of ill **health**.

There are numerous anecdotal reports of self-medication from the natural world; **elephants**, for example, and other herbivores will ingest soil (**geophagia**), which assists digestion by helping to absorb toxic, plant-derived alkaloid compounds. Similarly, laboratory **rats** will eat clay in response to gastrointestinal malaise. Detailed observational studies have also shown a correlation between **parasite** infestation and ingestion of certain plants. For example, the plant *Vernonia amygdalina* is not routinely ingested by **chimpanzees** despite it being widely available within the local habitat. However, individuals have been observed to ingest the bitter pith of the plant when showing signs of parasite infestation and after consumption symptoms have reduced. Worms have been noted with the leaves, suggesting that either the plant acts to enhance mechanical expulsion in some way or contains anti-parasitic compounds.

Whether animals actually actively seek out and consume certain foods when sick still remains to be resolved. However, when provided with substances with medicinal properties or drugs and the opportunity to learn about their effects, there is compelling support for the hypothesis that animals can learn to self-administer medication to alleviate **pain** or other symptoms of ill health. Under controlled conditions, one study found that sound and lame broiler **chickens** were trained to discriminate between two differently coloured feeds, one of which contained carprofen (a non-steroidal anti-inflammatory drug with analgesic properties). The lame birds ingested more of the medicated feed than the sound birds, and the amount of carprofen consumed increased with the severity of **lameness**, suggesting that these birds had learned to self-medicate to reduce the pain of lameness.

Self-mutilation

Self-mutilation is apparently directed, repetitive behaviour resulting in self-induced **injury**, often referred to in the literature as a stereotypy, an obsessive-compulsive behaviour, or simply a compulsive behaviour. Some form of self-mutilation has been described in many domestic species, ranging from excessive self-barbering in laboratory rodents, incessant licking or biting in **dogs**, self-directed biting or kicking in **horses** and **feather plucking** in birds. The behaviour and resulting injury not only affect the **health** and behavioural **well-being** of the animal, but can be detrimental to the **human-animal bond**.

Self-mutilation may be traced to an original physical or environmental **aetiology**. Often, however, the behaviour continues long beyond, and independent of, the inciting stimulus. The neurochemical basis for development or maintenance of self-mutilation has been traced to the dopaminergic, serotonergic and opiate neurotransmitter systems in various species studied, resulting in an associated pharmacologic component to the overall therapeutic plan.

Horses

In horses, self-mutilation has been observed in association with pain emanating from the gastrointestinal tract, urogenital tract or other anatomical site. Removal of the primary source of pain usually eliminates the self-mutilation behaviour. It is most commonly seen, however, in intact male horses, both intensively managed and in rather extensive turnout situations, so clearly not the product of any specific confinement situation. These horses may bite themselves in the chest or pectoral area, forelimbs, thorax, flanks and tail or may strike or kick at walls or other solid objects, resulting in injury to their fore or hind limbs. This form of self-mutilation has been described as self-directed inter-male **aggression** (Dodman *et al.*, 1994). That is, the behaviours involved appear to be similar to those observed in natural inter-male agonistic encounters. Exposure to the sight or scent of other stallions (such as at turnout, in a stall or trailer, or associated with a multi-user faecal pile in a pasture or lot) or exposure to mares might trigger an episode of self-mutilation. In other cases it might be noted that the stallion or gelding has been thwarted in normal **sexual behaviour** opportunities.

Provision of environmental changes to reduce exposure to triggering stimuli or to establish more frequent normal sexual behaviour opportunities may reduce the behaviour, but rarely abolishes it. **Castration** is a consideration, though it may not be a preferred option for the owner or manager due to economics; castration is not always reliable in reducing or eliminating the behaviour. Attempting to simply reduce the horse's ability to reach the affected areas on its body, such as placing a neck cradle, may result in the horse redirecting the behaviour towards injuring another part of the body, or incurring secondary injuries related to the device or barrier itself. Single-subject reports have cited the success of management changes such as decreased concentrate and increased roughage diets, exercise and provision of a **goat** as a companion, and a pharmacologic approach via the use of a specific **opioid** antagonist.

Psittacines

Companion psittacine birds are prone to the self-mutilation behaviour known as feather plucking. In this behaviour, birds will pick and remove all accessible **feathers** and may then begin to self-injure their skin, resulting in chronic wounds. The increased incidence of feather plucking in certain species suggests a possible genetic basis. There are various pain-related, dietary and systemic medical aetiologies. Commonly, though, the management and care of the caged bird results in social

deprivation, **social group** (in which humans may be included) disorder or lack of other appropriate environmental stimuli failing to meet the bird's behavioural needs (Jenkins, 2001).

Treatment for feather plucking includes managerial changes such as providing appropriate environmental **enrichment** devices, activities and behaviour modification techniques to affect the bird's response to stressful situations. Pharmacologic therapy and physical means to prevent the behaviour are largely ineffective without appropriate management changes.

Canids

In domesticated dogs, self-mutilation is often presented as lick granulomas or acral lick dermatitis, but many other forms of self-injurious biting and scratching are also seen. Some of these behaviours seem to be breed or group specific. As in other species, the aetiology may be found in an inciting pain or allergic stimulus, such as in the case of a dog that begins to lick at an allergic dermatitis or surgical wound, and the behaviour continues beyond physical resolution of the problem or on to unaffected areas of the body. In other cases the inciting stimulus is conflict, **frustration** or **fear** associated with **confinement**, **housing**, **restraint**, inconsistency in management or **handling** or disorders of social interactions with other dogs or humans (Luescher, 2003). Owners may inadvertently reinforce the behaviour, and thus it may become a conditioned response. Attempted distraction may interrupt or aggravate the performance of the behaviour.

Management and behaviour modification techniques to resolve this include: (i) removal of an offending environmental stimulus; (ii) desensitizing the dog to the stimulus; (iii) increasing structured activity and exercise; and (iv) counter-conditioning training. Clomipramine, a tricyclic antidepressant drug, has been used in several **companion animal** species with behaviours classified as **compulsive disorders**. With this or any pharmacologic treatment, the duration of use must be adequate to observe an effect, behaviour modification and management techniques should be instituted and the animal should be weaned slowly off the medication, with a return to effective levels should the behaviour recur in the interim.

Humans

For the animal specialist, it is instructive to note that researchers and clinical therapists have described medical/physiological,

P.540

psychological and social aetiologies for self-mutilation or self-injurious behaviour in humans. Along with behaviour modification therapy, use of pharmacologic treatments for self-mutilation in humans, based upon the suspected aetiology or other accompanying disorders, includes endogenous opioid antagonists, selective serotonin reuptake inhibitors and several classes of anti-depressants.

Selye, Hans

Hans H.B. Selye (1907-1982) is best known for coining the term '**general adaptation syndrome**' to describe the similar physiological **stress** response mounted by the body in relation to a range of **stressors**, and his extensive work in the role of a range of stressors in physical **disease** manifestations led to him being called the 'father of stress'. Indeed, the word

'stress' was introduced into both the French and German language as a direct result of his work, since no native equivalent existed at the time of his initial presentations in these countries. As a medical endocrinologist, his work has been instrumental in the recognition of the influence of psychological factors on human health, but it has also been very influential on the perspectives taken by many on **welfare measurement** in animals. His initial experimental evidence reputedly came from an initial problem associated with the poor **handling** and husbandry of animals involved in an endocrinological experiment, in which both treatment and control animals showed similar adrenal enlargement, atrophy of the thymus and gastrointestinal ulceration.

(DSM)

Semiochemical

A semiochemical is a chemical substance secreted by an organism with the purpose of carrying messages that may be interpreted by either members of the same species (intraspecific) or different species (interspecific). **Pheromones** are examples of intraspecific semiochemicals that can carry information regarding sexual receptiveness, locations of food sources, **territory** boundaries and dangerous situations.

Sensitive phase

Sensitive phases refer to the stages of an animal's life in which the animal is particularly sensitive to certain types of experience or stimuli, and the concept is gradually replacing the older idea of **critical periods**. Sensitive phases have gradual beginnings and ends (hence the preference for the term 'phase' over period, which implies a more abrupt start and finish) and, while they are the period of maximum sensitivity in which the appropriate experience may occur, the correct behaviour can still be learned at a later stage (thus they are not as 'critical' in development as originally believed).

(LMD)

See also: Development of behaviour; Preparedness

Sensitization

The process by which an individual reaches a period of increased reactivity following repeated experience of a **stimulus**. If an individual experiences a series of arousing positive or negative stimuli, sensitization describes the likelihood that they will respond more quickly or with more intensity to this or another stimulus that is presented soon after. For example, rats that are repeatedly given small electric shocks will show a heightened response to this or any other arousing stimulus for a period of time.

Sentience

Sentience is the capacity to perceive or feel things, one of several aspects of **consciousness**. Sentience refers to the response of the **central nervous system** to activation of the peripheral sensory system. A sentient being is one that has its own experience of life, meaning that 'there is something it is like' (Nagel, 1974) to be that being. Sentience is sometimes termed 'phenomenal consciousness and awareness of (the quality of) sensory input is an important aspect of sentience'. The mainstream view in Western society is that at least vertebrate animals are sentient. Most countries' animal protection legislation includes all vertebrates, but no (or only exceptional cases of) invertebrates. In the European Community, the Treaty of Amsterdam explicitly refers to sentience in its statement that the member states desire to 'ensure improved protection and respect for the welfare of animals as sentient beings'.

The question of sentience is central for bioethics and animal **welfare** research, because it provides the fundament for important considerations over how individuals should be treated - viewing animals as sentient is a major reason for many people to be concerned about how animals are treated. However, the scientific understanding of sentience (human and animal) is still limited. Present knowledge of neurobiology is not able to explain consciousness in terms of material

mechanisms of the nervous system. The discrepancy between the subjective consciousness experienced (and assumed to exist in other beings) and what is known about the mechanisms potentially is sometimes termed the 'explanatory gap'. As long as the explanatory gap persists, there will be considerable philosophical disagreement and uncertainty about sentience.

Philosophical theories that consider any kind of consciousness dependent on capacity for **language** or capacity for second-order thought will determine animals as non-sentient. According to this view, defended by philosophers such as Peter Carruthers, whether animals are sentient cannot be determined. The mainstream view in biology is less sceptical. Although it views sentience and other aspects of consciousness as essentially private - that is, they can only be experienced from within - it is possible to assume that other individuals are sentient, based on their behavioural and physical similarity to us. While the assumption is uncontroversial for adult human

P.541

beings, when aiming to extend the assumption to non-human animals the issue becomes more complicated, as verbal account is not available, and the behavioural and physical similarities are smaller.

Even though common sense may suggest sentience in many species, a scientific argument for attributing sentience must be based on systematically collected evidence. Such a systematic approach is suggested by Smith and Boyd (1991) - to find out whether animals of a particular kind are sentient we can ask whether these animals have anatomical, physical and biochemical mechanisms similar to those we know are essential for human subjective experiences, and whether the animals behave in similar ways to experiencing humans. The authors synthesize this into a list of neuroanatomical/physiological and behavioural criteria for determining the capacity to experience **pain**, **stress** and **anxiety** in non-human animals. For any of these experiences, this list includes the possession of higher **brain** centres and evidence of behavioural reaction towards potentially nociceptive, anxiogenic or stressful experiences. Further evidence is added if these behavioural reactions are modulated by drugs that have a known anxiolytic or analgesic effect in humans. In addition, one should look for peripheral nervous structures (including receptors, **signal** substances and hormones) for each specific type of reaction. The more of these criteria that are fulfilled, the more evidence there is to support the view that an animal is indeed sentient.

Sentience is the fundamental criterion for moral consideration in utilitarian **ethics** (see: **Utilitarianism**), and is also central for the subjectivist or hedonist view of animal welfare. It also plays an important indirect role in the animal rights ethics proposed by **Tom Regan**, as only sentient beings are considered 'subjects of a life' and hence worthy of consideration. Even though he has strongly argued against attributing sentience to animals, in later texts Peter Carruthers has affirmed that animals nevertheless should be given moral consideration.

The other important aspect of sentience for animal ethics and animal welfare is the *quality* of the subjective experience. Because animal welfare science and animal ethics have been predominantly preoccupied with identifying and preventing negative experiences, the question of sentience has often been reduced to a question of capacity to feel pain, stress and anxiety. It is not immediately obvious that the interest in avoiding negative experiences is always greater than the interest in having positive experiences, as humans may be prepared to go through unpleasant and often painful experiences (the training required for international sports performance being one example) to gain later positive experiences, and few humans would probably opt for a life without pain if it meant a life without gain.

Nevertheless, given that animal welfare legislation at this point is primarily concerned with reducing animal **suffering**, it seems valid to maintain focus on negative experiences. Much animal welfare research addresses the quality of subjective experiences only indirectly, assuming a relation between absence of negative experiences and good health, possibility to express motivated behaviours and the absence of stress reactions. Later approaches have attempted to come closer to a direct measure of the sentient experience, by studying behaviours as expressions of mental states (see Wemelsfelder, 1997) and through the adaptation of tests from human clinical **psychology** into non-linguistic cognitive measures of animal **emotion** (see Paul *et al.*, 2005).

Separation anxiety

Separation anxiety refers to the feelings of **anxiety** generated by the impending or actual separation of an individual from one to which it has a close relationship. It is classified as a disorder when the response interferes with normal functioning, e.g. the individual cannot be left alone for short periods of time or shows signs of panic or self-harm. The term 'separation anxiety' was widely used in the first English language texts in the field of veterinary behavioural medicine to describe a range of **problem behaviours** in **dogs** relating to destructiveness, **vocalization**, **elimination** and hyperactivity in the owner's absence. It has been suggested that the condition may affect up to 50% of dogs in the UK at some time. The condition has since been reported in a range of species, including **cats**, which might not typically be considered gregarious.

More recently, it has been recognized that there are a range of aetiological and potentially mechanistic processes that might play a part in the development of such distress, such as: (i) the level of **attachment** the animal exhibits towards a particular person; (ii) the association of owner departure at a particular time with a previously traumatic event; and (iii) the capacity of the animal to cope with isolation per se and its level of trait anxiety (**see also: Temperament**). This has led some to abandon the term 'separation anxiety' for the general presentation of **distress** when left alone in favour of the terms 'separation-related problems' or 'separation-related disorders', and less commonly terms like 'separation distress', 'separation-related anxiety' and 'separation stress syndrome'. The rationale here is that the term 'separation anxiety' implies a single emotional element dimension to the presenting problem, when in fact the presenting **sign** may have diverse emotional foundations.

P.542

In France, there is a distinctive approach to veterinary behavioural medicine encapsulated largely by Pageat's (1995) text, *The Behavioural Pathology of the Dog*. In this text, a distinction is made between 'separation anxiety', a condition arising from a failure of the puppy to full development detachment from its maternal figure, and 'hyperattachment', an attachment that usually develops against a background of **depression**. Thus the French school approach tends to emphasize signs relating to an absence of adult behaviours and an early age of onset in separation anxiety, while others tend to refer to signs of over-attachment. However, there are no peer-reviewed scientific publications based on empirical studies to support the distinction made in France, or any difference in the general treatment strategies employed.

One recent study using a modified human test of attachment (**see: Secure base hypothesis**) concluded that separation anxiety is not based on hyper-attachment per se, although no attempt was made to subcategorize affected subjects on the basis of potentially clinically relevant aetiological factors such as those discussed above. However, it is acknowledged that the problem may be related to a different style of attachment, rather than hyper-attachment. This hypothesis is supported by retrospective data on behaviours associated with separation anxiety, which suggest that dogs with separation anxiety

tend to follow their owner excessively and excitedly greet the owner upon his/her return for a longer period. This might indicate that the nature of the interactions between owner and dog, rather than the level of attachment per se, is important to the expression of the problem.

Sepsis

Strictly speaking, sepsis describes a generalized immune reaction to infection and is an often fatal condition. The term is often erroneously applied to infectious conditions in which the pathogen is circulating via the blood. This latter condition is more accurately referred to as a septicaemia (blood poisoning), which may lead to sepsis but not necessarily so.

(DSM)

Serotonin

Serotonin (5-hydroxytryptamine, 5-HT) acts as a monoamine transmitter as well as a neuromodulator in the **central nervous system** (CNS). It is synthesized from the aromatic amino acid L-tryptophan by the enzyme tryptophan hydroxylase (the rate-limiting step) to 5-hydroxytryptophan (5-HTP), and by an amino acid decarboxylase (non-specific enzyme) to 5-HT. 5-HT is metabolized by monoamine oxidase (MAO) to 5-hydroxyindoleacetic acid (5-HIAA).

Following synthesis, 5-HT is transported to the nerve terminals and stored in synaptic vesicles. It is released into the synaptic cleft by exocytosis in response to depolarization of the axon terminal (action potentials). Released 5-HT is coupled to the 5-HT receptors to stimulate postsynaptic **neuron(e)s**. The deactivation of 5-HT is achieved by its re-uptake into the presynaptic terminals, uptake by astrocytes and metabolism by MAO to 5-HIAA. The release of 5-HT from neurons is regulated by axon traffic, while maintenance of the content of 5-HT in the CNS is regulated by multiple factors, including the availability of precursor L-tryptophan, auto- and hetero-receptors, activity of enzymes and functions of astrocytes.

The distribution of 5-HT in the CNS forms a diffuse network. The cell-bodies of the serotonin neurons are mainly found in the raphe nucleus of the brainstem. Axons of the 5-HT neurons arising from the dorsal raphe nucleus innervate the cerebral cortex and the neostriatum; the median raphe nucleus innervates the limbic system; the rostral raphe nucleus innervates the forebrain regions; whereas the caudal raphe nucleus projects within the brainstem and the spinal cord with some overlap.

Serotonin mediates biological processes by interacting with its receptors. There are seven subtypes of 5-HT receptors, 5-HT₁₋₇, which have been recognized through various studies using selective agonists and antagonists, radio-ligand-binding analysis and identification of receptor genes. Several subpopulations for some of these receptors, such as 5-HT_{1A-1F} and 5-HT_{2A-2C}, have been grouped according to operational, structural and transductional properties. Each type and subtype of receptors has been implicated as playing important roles in physiological, pathological and psychopathological conditions.

Based on the broad distribution of 5-HT and its receptors in the CNS, 5-HT has a wide range of biological functions in controlling physiological homeostasis, including **pain** reaction, **thermoregulation**, **sexual behaviour**, motor activity and appetite (**feeding**, **hunger** and energy **homeostasis**). Serotonin also plays important roles in controlling states of **consciousness**, such as **sleep**, **memory** and mood, as well as various neuropsychiatric disorders such as **aggression**,

violence, **anxiety**, **depression**, migraine and drug abuse. Through regulation of the **hypothalamic-pituitary-adrenal (HPA) axis**, 5-HT regulates the neuroendocrine control mechanisms in the HPA axis in releasing **prolactin** and **growth hormone (GH)** during **reproduction**, and **ACTH** and **corticosteroids** in response to **stressors**, such as environmental danger or threat.

Serotonin regulates the transmission of painful stimuli at both the dorsal horn and the brainstem sites, especially in the periaqueductal grey matter. Exogenous intracerebroventricular administration of 5-HT exhibits an analgesic effect (**see: Analgesia**). The analgesic effects are confirmed following administration of drugs that enhance 5-HT transmission - for example, blockers of reuptake such as zimelidine and clomipramine.

Depletion or decrease of 5-HT concentrations, ratio of 5-HIAA:5-HT or metabolism of tryptophan have all been implicated in neuropsychiatric abnormalities such as cognitive decline, mood disorders and depressive symptoms, especially in long-lasting and chronic **diseases**. Depression can be worsened by experimental depletion of 5-HT via a tryptophan-depleted diet. In contrast, selective 5-HT re-uptake inhibitors, such as fluoxetine, have proved to be effective antidepressants.

P.543

Brain serotonin functions as an inhibitory factor of aggression. Depletion or decrease of 5-HT concentrations and ratio of 5-HIAA:5-HT have been implicated in aggressiveness, and violence in human and animals and **cannibalism** in rats.

Experimental studies in animals have shown that **domestication** of rats selected for tame behaviour towards humans has resulted in increased levels of 5-HT and 5-HIAA in the midbrain and **hypothalamus**. Experimental increase of 5-HT and/or 5-HIAA in the brain regions, such as in the lateral hypothalamus and amygdala, blocks or retracts killing behaviour in rodents. 5-HT has also been highlighted as an important factor in the **stress** response, and low levels of endogenous 5-HT (or its metabolites) have been associated with depression and suicidal behaviour.

There are correlations between 5-HT activity and impaired impulse control and stress-related aggression in adolescents who suffer from mental retardation. Administrations of compounds that specifically elevate 5-HT levels in the brain (e.g. fluoxetine) have been used effectively to treat depression and associated aggressiveness. In addition, previous studies have shown that functions of 5-HT₁ and 5-HT₂ receptors are linked to aggression. Aggressiveness can be increased due to impaired receptor functions or by knockout of 5-HT₁ receptor genes.

Serotonin has a tonic, inhibitory effect on sexual behaviour and reproduction, such as inhibition of **luteinizing hormone (LH)** secretion and ovulation. The effects of 5-HT on sexual behaviour are positively correlated to the stimulation of the pre-optic area (POA) and median eminence of the hypothalamus, and differently regulated by 5-HT receptors in rodents. Recently, the roles of 5-HT in modulating sexual behaviour have been reevaluated, and it is concluded that 5-HT can either inhibit or facilitate secretion of **gonadotropins**, sexual hormone release and sexual behaviour, depending on which brain regions are involved and what subtypes of 5-HT receptors are activated. Effects of 5-HT on sexual behaviour are positively correlated to the stimulation of the pre-optic area (POA) and median eminence, but negatively correlated to the stimulation of the ventromedial nucleus (VMN), zona incerta and arcuate nucleus. The 5-HT₂ receptors in the POA are involved in the stimulatory function of 5-HT, while 5-HT_{1A} receptors mediate the inhibitory role in the VMN. With systemic injection of the selective 5-HT₂ and 5-HT₁ agonists, MK 212 and Ru 24969, sexual behaviour is either facilitated or inhibited, respectively. In addition, inhibited sexual behaviour is effected by peripherally administered 5-HT₂ antagonist, pirenperone, and its effect is attenuated by the 5-HT agonist, quipazine.

Serotonin cannot pass the brain-blood barrier and is regulated differently in the CNS, the serotonergic neurons, peripheral tissues and the platelets. The brain and blood could be assumed to be two compartments. Previous studies have found that there are no correlations of either MAO activity or 5-HT levels between brain and blood.

Although supplemental tryptophan, a precursor of 5-HT, decreases aggression in feed-restricted male chickens, the effect of tryptophan on modification of aggression is related to centrally enhanced neuronal firing rather than peripherally increased 5-HT resulting from conversion of tryptophan. However, blood 5-HT concentration could functionally be a monitor of the changes of the central 5-HT system, as the 5-HT systems between blood platelets and serotonergic neurons share some of anatomical and functional similarities, including the active carrier mechanism, intracellular storage, receptors and binding sites. In addition, 90% of cerebral 5-HIAA is released directly into the blood.

Analysis of blood levels of 5-HIAA may directly or indirectly provide clues of the changes of the CSF 5-HIAA and brain 5-HT. Platelets have been proposed as a peripheral tool for observation of a central 5-HT system. Further studies are needed to examine the cellular mechanisms of regulating 5-HT systems between the periphery and the brain, and to determine how each functions in affecting animal behaviour and adaptation, and their correlations.

Service animal

A service animal is defined by the American Disabilities Act as ‘any guide dog, signal dog or other animal individually trained to provide assistance with a disability’, and this definition may be usefully employed in science. Service animals perform some of the functions and tasks that disabled human individuals cannot perform themselves. Examples include guide dogs for the blind, hearing dogs for the deaf, seizure alert dogs and mobility assistance dogs. In some contexts the term may also be applied to ‘working animals’ such as military dogs.

(EP)

Sex differences

For all animals, including humans, sex differences exist in the behaviour, morphology (sexual dimorphism) and physiology of males and females. For example, the primary sex organs of males and females differ, and the same can be said about their brains and behaviour. The physiological mechanisms that mediate most sex differences in brain function are attributed to differences in the gonadal hormone secretion and action among males and females. However, recent work has shown that sex differences can be induced by external sources of gonadal steroids and by sex chromosome genes directly affecting the brain. The evolutionary processes that led to differences between males and females are ultimately a consequence of anisogamy (differences in the gametes). Anisogamy has led to sex differences in morphology, behaviours and possibly **cognition**. Differences in these phenotypic characteristics have provided the substrate for natural selection and **sexual selection** to bring about differences between the sexes.

Sexual differentiation

Sex differences are usually attributed to genetic differences between males and females. In mammals, females have two X chromosomes and males have one X and one Y chromosome. Many of the cells in neural substrates, especially those associated with the brain, also differ in genetic sex. Genetic sex, however, is only one factor that will influence sex differences. Several studies have shown that hormones constitute an important internal causal factor that can affect the behaviour, morphology, brain and physiology of males and females. The sex differences may be expressed early in development, during the prenatal or early postnatal periods, when hormones organize neural and endocrine substrates or sex differences may be manifested late in development, during

P.544

puberty, when hormones activate mediation of neural and endocrine substrates.

Most sex differences in brain function are attributed to differences in the gonadal hormone secretion and action among males and females. In mammals, for example, the presence of a Y chromosome induces the formation of the testes. The testes produce a surge of **testosterone** during fetal development and neonatal life. This testosterone surge causes masculine neural development, at least in mammals, and creates a phenotypic male. Testosterone and other **androgens** also cause the transformation of the genitals into male organs and the organization of male-like behaviours. If a male rodent pup is castrated or treated with an anti-androgen shortly after birth, as an adult it will not display, or have, suppressed male-typical behaviours such as mounting, but will display female-like behaviours such as **lordosis**.

The absence of a Y chromosome results in the formation of ovaries and a phenotypic female being produced. In mammals, morphology, physiology and behaviours typically associated with females develop in the absence of testosterone. If androgens are administered to female rodent pups shortly after their birth they will display, as an adult, more male-like behaviours and fewer female-like behaviours. In birds, the situation is more complicated and reversed. Males are the default sex and a surge of estradiol around hatching feminizes the neural development of female birds.

External steroids - those not produced by the animal's own sex organs - can affect sexual differentiation in mammals and birds. Birds still in the egg can be exposed to large quantities of testosterone deposited in the egg yolk by the mother. It has been suggested that the mother can actively regulate the amount of testosterone in the egg yolk, which in turn affects the behaviour of the young after they hatch. In rats, mice and probably other rodents, intrauterine position can affect how females will behave as adults. Females that are surrounded on either side by brothers during development are more likely to be exposed to the testosterone produced by them. These females, known as 2M (M = male) females, are more likely as

adults to display more male-typical behaviour and fewer female-typical behaviours as compared with females that were surrounded *in utero* by sisters (0M female) or by a sister and a brother (1M female).

This picture of sexual differentiation, however, is more complex than originally thought. Recent work has shown that, in a finch and some transgenic mice, the sexual phenotype may be insensitive to the effects of sex hormones during development, or that sex differences occur prior to the onset of sex-specific patterns of gonadal hormone activity. These findings suggest that sex chromosome genes acting within particular brain cells could contribute to their sexual differentiation.

Anisogamy

Differences between males and females are ultimately a consequence of sexual reproduction and anisogamy. Theoretical models suggest that, soon after the beginning of sexual **reproduction**, there was a process of disruptive **selection** that ended in the differentiation of gametes, or anisogamy. Briefly, larger gametes produced **zygotes** with higher survival as compared with zygotes produced by smaller gametes. The reason is that larger gametes have more nutrients for the development of the zygote. Thus, there was a selective pressure for the production of progressively larger gametes, even though this implied the production of fewer gametes, assuming a relatively fixed amount of resources. At the same time, there was another selective pressure favouring small gametes that were able to swim fast and find a larger than average gamete before other competing gametes did. These small and fast gametes, sperm, were basically parasitizing larger gametes, including their DNA in the zygote without offering any nutrients. Because these small gametes were cheaper to produce, individuals producing them were able to do so in large quantities.

The final result of disruptive selection for both small and large gametes favoured the extreme anisogamy that we observe in animal species, with small and mobile gametes (sperm) produced in large quantities, and large and sessile gametes, eggs, produced in small quantities. Males, producers of sperm, are the sex that seeks mates more actively, whereas females, producers of eggs, are the receptive sex. Moreover, males are often the limited sex, whereas females are often the limiting sex with regard to mating opportunities.

Sex differences in behaviour

The fact that males produce numerous and cheap sperm, while females produce few and expensive eggs, has two important consequences. First, the potential reproductive success of males and females is entirely different. A male may potentially fertilize many females, whereas females are limited by the number of eggs, and thus offspring, that they can produce and raise. Males, thus, will benefit by trying to fertilize as many females as possible, and will compete among them for access to reproductive females, a process called male-male competition. In contrast, females will benefit by mating with the best mate possible, i.e. the mate that will maximize their fitness. Both mate choice and male-male competition are strong evolutionary forces responsible for much of the observed sexual dimorphism. Such characters as weaponry, large body size and heightened **aggression**, generally male characteristics, are a result of male-male competition (**see: Intrasexual selection**). Additionally, females may amplify the development of male characters via **mate choice**, because such characters as bright plumage, complex **vocalizations**, reckless behaviour or large body size may be indicators of male quality (**see: Intersexual selection**).

When females show a preference for elaborate and extreme traits, there may be directional selection favouring those extravagant traits in males, which will also result in high sexual dimorphism. A confirmation of the importance of sexual selection (mate choice and male-male competition) in the production of sexual dimorphism is the fact that in monogamous systems, in which sexual selection is relatively weak, sexual dimorphism is less apparent than in non-monogamous systems.

A second consequence of the initial difference between males and females (i.e. production of either sperm or eggs) is a sexual difference in parental investment. Because males' initial investment is relatively low and their reproductive success may be improved by further mating, they will generally opt for not providing any other parental investment than their gametes.

Females, because of their initial larger investment, are therefore forced to provide much of the parental care to their offspring (**see: Parental investment**). This is the reason why maternal care is generally much higher than paternal care, and is an illustrative example of sexual conflict, which occurs when benefits and costs of reproduction are asymmetric for males and females, and thus each sex will behave in such a way that maximizes its own **fitness** to the detriment of the other sex's fitness.

Sexual differences in behaviour are also dependent on phylogenetical constraints. Whereas in mammals and birds the chromosomes of an individual will determine the sex, in many reptiles incubation temperature determines an individual's sex, and some fish species may change sex in response to their social environment. Furthermore, females are the heterogametic sex in birds, whereas males are the heterogametic sex in mammals. Similar differences are found in relation to philopatry and dispersal. Whereas females are the philopatric sex in mammals, female birds are the dispersive sex.

Sex differences in cognition - a case study in voles

Several studies have reported sex differences in cognition in humans, but little is known about sex differences in cognition among non-human animals. Recently, a study to determine whether meadow voles (*Microtus pennsylvanicus*) were able to distinguish between areas containing varying numbers of over-marks from two scent donors, suggesting a capacity for relative numerosness, has been reported (Ferkin *et al.*, 2005). Over-marks are formed when two scent marks overlap, and is a common feature of **scent marking** in voles. It is possible to test for relative numerosness by allowing voles to explore an area that contains a set of over-marks by one individual and a smaller or larger set of over-marks by another individual. If voles displayed the capacity for distinguishing more from less, they would respond preferentially to the donor which was the top-scent donor on more of the over-marks as compared with the donor that was the bottom-scent on most of the over-marks.

Female voles were better than males at spontaneous discrimination of more frequent versus less frequent top-scent donors. Females were capable of spontaneously discriminating between areas in which donor A's marks were on top of donor B's marks four times relative to the three times donor B's marks were on top of donor A's marks. Males could make a similar discrimination if donor A's marks were on top of donor B's marks six times relative to the one time donor B's mark was on top of one of donor A's marks.

This type of asymmetry in relative numerosness by voles is interesting, in that the literature is replete with studies suggesting that sex differences exist in mathematical skills that favour males over females, particularly in primates and humans. One argument is that males have better spatial and navigational abilities than females, which provides them with a greater capacity to solve problems in geometry and other mathematics-related activities. It is intriguing that male meadow voles have better spatial ability but worse prenumerical ability than female meadow voles. The findings suggest that sex differences in distinguishing more over-marks from fewer over-marks are somehow separate from the spatial ability of meadow voles. Moreover, for voles it appears that spatial ability may be a poor predictor of relative numerosness, and vice versa. Female biases in relative numerosness may be the developmental link for more complex numerical processes, such as subitizing, estimation, counting and arithmetic reasoning in this species.

Recency in areas and dominance status may both be features of the top-scent donor and attributes of males that sire offspring in voles. In that male voles wander through large **home ranges** that encompass the territories of one or more females, resident females may be able to select potential mates based on asymmetries in the number of times that a particular male was the top- or bottom-scent donor in their **territory**. Females may need to distinguish between and remember the individuals that may enter their territories in order to keep track of them. In contrast, males are not territorial and may not need to respond to over-marks, as do female voles. Thus, female voles may have a better 'memory for scent marks' relative to male voles. Alternatively, female voles may be more responsive than male voles to asymmetries in the relative number of top- and bottom-scent marks in an area, because the top-scent mark conveys greater or more salient information to females relative to that of the bottom-scent marks. At this point in time, it is not clear why male voles cannot distinguish small asymmetries in the relative number of over-marks of female **conspecifics**.

Sexual behaviour

Sexual behaviours are designed to ultimately result in the deposition of sufficient viable spermatozoa in the reproductive tract of the female at the optimum time of the oestrous cycle to ensure conception. Male farm animals are often required to mate frequently (to reduce costs, maximize genetic gain, etc.) and, thus, level of sexual behaviour is especially important to the value of these animals. When males are mating frequently, the reserves of sperm in the epididymides are depleted, resulting in the need for females to be mated more than once to ensure conception. Furthermore, males are often required to mate a large number of females in a short period. Sexual behaviour therefore is clearly important from the perspective of both the species and the farmers or owners of domestic animals. This commentary will consider the characteristics

P.546

and regulation of the sexual behaviour of our common domestic animals.

Male sexual behaviour

There are two major characteristics of males that affect the likelihood of achieving copulation, sexual motivation and mating competency. Sexual motivation, sometimes referred to as libido or sexual drive, refers to the tendency to copulate. Mating competency, sometimes referred to as mating dexterity, is the ability to copulate, that is the ability to mount, gain an erection of the penis, thrust and achieve intromission.

Male sexual behaviour is obviously necessary to achieve impregnation in natural mating systems. Furthermore, the level of male sexual behaviour may affect the level of reproductive performance such as the number and timing of offspring produced, which has clear economic implications. The level of sexual behaviour of rams and bulls in competitive and uncompetitive natural mating systems will affect numbers of females mated and pregnancy rate. Furthermore, some studies have shown that a high level of sexual behaviour in bulls can lead to greater weaning or marketing weights, because the offspring are born earlier.

Male sexual behaviour is quite varied, although the essential features of intromission, pelvic thrusting and ejaculation are characteristic of all male mammals. One of the behavioural components of male sexual display in all hoofed livestock, except the pig, is the 'olfactory reflex' known as the flehmen. The animal fully extends its head and neck, contracts its nares and raises its upper lip while taking shallow respirations. Flehmen normally occurs following the smelling of urine and nosing the ano-genital region of the female, and is considered a form of urine testing. Olfactory and gustatory stimuli are used in these species to assist in detecting oestrous females.

A number of components of male sexual behaviour are common to a number of species, such as nosing the perineum, nudging, flehmen, flicking the tongue, striking out the fore limb and low-pitched bleats in **sheep** and **goats**. Other components of male sexual behaviour are reasonably specific to an individual species. For example, boars generally utter a short series of characteristic grunts and clamp their jaws, producing saliva, while their heads are held in close proximity to that of the female. Boars will also vigorously nose the flanks of females during courtship.

Hormonal and neural control of male sexual behaviour

The hormonal and neural control of sexual behaviour has been most studied in laboratory species, particularly the **rat**. Some elegant research by Frank Beach in the 1940s and 1950s with rats and **guinea pigs** clearly demonstrated the critical

role of the gonadal hormone **testosterone**. Testosterone is necessary to elicit sexual behaviour: **castration** diminished sexual behaviour, with the extent dependent on age and/or sexual experience. This research also indicated that a threshold concentration of testosterone is required to elicit sexual behaviour and, above this threshold, the concentration of the hormone is ineffectual in increasing copulatory behaviour. In addition to maintaining sexual behaviour, androgens stimulate the latter stages of spermatogenesis and prolong the lifespan of epididymal sperm. They also promote the growth, development and secretory activity of the sexual accessory glands of the male.

Most males have sufficient testosterone, and thus most male sexual behaviour problems are not due to low testosterone concentrations. However, in those species where there is a seasonal fluctuation in sexual behaviour, such as **horses** and **sheep**, there is a corresponding fluctuation in testosterone secretion. Studies by Beach showed that pre-castration differences in copulatory behaviour still existed after testosterone therapy, indicating the impact of genetics and experience on the control of male sexual behaviour.

Some sexual reflexes, such as erection and ejaculation, are organized by neural circuits in the spinal cord. In some laboratory studies, it has been shown that the ejaculatory response is normally inhibited by **neuron(e)s** in the **brain**. The medial preoptic area is the forebrain area most critical for male sexual behaviour. Stimulation of this region produces copulatory behaviour, while lesions abolish it. Implantation of testosterone directly into this area reinstates copulatory behaviour that had previously been abolished by castration in adulthood. Autoradiography studies show that neurons in the medial preoptic area contain testosterone receptors.

Factors affecting male sexual behaviour

A number of factors can affect male sexual behaviour, such as genetic, seasonal, social, sexual and psychological factors. **Breed** effects are apparent in many farm species. For example, dairy bulls generally display higher levels of sexual behaviour than beef bulls. Research on **cattle** and several laboratory species indicates that level of sexual behaviour is moderately heritable. The considerable variability in male sexual performance, with many individuals exhibiting low levels of sexual behaviour and mating competency, may be in part due to relaxed genetic selection for sexual performance in non-competitive captive populations.

Seasonal effects are evident in some species, such as **sheep**, **cattle**, **horses**, **goats** and **dogs**, with reproductive activity intense during the breeding season and subdued or absent during the remainder of the year. **Photoperiod** is the principal external agent controlling sexual activity in seasonal breeders. Adverse temperature effects, particularly high temperatures, on sexual behaviour are apparent even in constant breeders such as **pigs** and **rabbits**.

Social and sexual effects on male sexual behaviour can be profound. The social environment during rearing can have marked effects on the development of the sexual behaviour of boars. Social contact, particularly tactile contact with other pigs, has been shown to be influential in the development of high levels of sexual behaviour of boars. Both heterosexual sexual experience and age influence the sexual behaviour of rams. Cockerels isolated from pullets and individually reared from an early age show diminished sexual behaviour in adulthood in comparison with males reared in all-male **groups**.

Depriving mature boars of female contact, possibly through reduced olfactory stimulation, will depress but not eliminate the sexual behaviour of mature boars; however, this effect is not permanent since the sexual behaviour of mature boars can be restored within 4 weeks of housing near female pigs. In contrast to the effects on mature boars, deprivation of female contact at the time of puberty may have adverse long-term effects on the sexual behaviour of boars. The oestrous status of the female

P.547

does not influence the effectiveness of females in stimulating the sexual behaviour of pubertal and mature boars, and olfactory - and perhaps auditory - stimuli from the female are most likely implicated.

Sexual stimulation, through observation of other animals mating, can increase short-term levels of sexual behaviour in males, but the presence of dominant males, even when physically separated, can inhibit the sexual behaviour of rams and bulls. Males generally show a refractory period or quiescence following copulation, in which the sexual stimulus properties of the female are less effective. However, successive introduction of 'new' or unfamiliar females can often re-initiate and maintain sexual activity for long periods in roosters, boars, rams, bulls and buck goats, a phenomenon called the 'Coolidge effect' (see: **Biostimulation**). This phenomenon is clearly valuable for species in which a single male inseminates all the members of his harem.

The incidence of '**buller-steer syndrome**', in which a steer is repeatedly mounted by other steers to the extent where it may be injured or even killed, is estimated at 1-3% with a resulting mortality of 1% in North American feedlots. The animals

ridden ('bullers') behave much like a female in **oestrus** by standing to be ridden. The causes of buller-steer syndrome are not fully understood, are conflicting and are controversial. Buller behaviour may be involved in the establishment and maintenance of a social hierarchy. However, additional contributing factors are the submissive behaviour of the buller, the use of various anabolic implants to stimulate growth, seasonal factors and the number of animals per pen.

Locomotor and penile injuries may not physically allow the achievement of copulation or may inhibit copulation because of pain, while injury sustained during copulation in many male farm animals may produce a psychological effect for some time after physical recovery has occurred, again inhibiting copulation. Obesity and skeletal defects - for example, in bulls and boars - affect sexual behaviour, often by affecting mobility and thus mating competency. Commercial **turkeys**, because of their broad-breasted breeding, are unable naturally to mate and so **artificial insemination** is a routine practice.

Poor orientation of the mounting response, such as side or head mounting, is often seen in young males. However, proper orientation is probably a learned response and, if the male is of satisfactory sexual motivation, mating competency should improve with the positive reinforcement of copulation.

Female sexual behaviour

Sexual behaviour of female farm animals is cyclic. By definition, females will mate only during oestrus, with the exception being induced ovulators, such as rabbits and **cats**, where mating induces ovulation. Three characteristics of female sexual behaviour that affect the likelihood of successful mating are attractivity, **proceptivity** and receptivity.

Attractivity refers to the extent to which the female evokes a sexual response in the male. Odours, visual characteristics and behaviour may affect attractiveness. Oestrous females generally are more attractive to males, although boars and bulls will mate restrained, non-oestrous (unreceptive) females. Rams prefer woolly ewes to shorn ewes, and older ewes are usually mated more frequently in competitive mating situations than are maidens.

Proceptivity refers to invitation or soliciting behaviour, and consists of affiliative behaviours such as male-seeking and physical appetitive behaviours such as signalling. Oestrous sows will vigorously seek boars, as well as mounting other females. Mounting cows indicate a sexually receptive female to bulls, although the presence of bulls can suppress mounting behaviour. About 90% of all mounted cows are in oestrus, but only 70% of all mounting cows. Sexually receptive ewes and nanny goats show increased activity and show an increase in non-specific bleats. Nanny goats tend to mount and be mounted by other females, but this is the exception in receptive ewes. Harems of ewes indicate sexual receptivity to rams. Oestrous mares approach stallions frequently, urinating and rhythmically everting their vulvas ('winking'), thus signalling their readiness to copulate. Female fowl may at times solicit mating by approaching the male, and female fowl prefer males with characteristics that indicate high fitness, such as symmetrical features or sexual secondary characteristics, e.g. large spurs or expansive decorative **feathers**.

Receptivity refers to the behavioural responses sufficient to enable copulation, such as the immobility response. Receptive sows show what is often called the 'standing response', which is the primary stimulus eliciting mounting in boars. Oestrous mares show a characteristic stance, with the tail lifted off to the side of the perineum, the head turned back to the stallion and one fore leg flexed. Oestrus is defined as the state during which the female accepts the male's copulation attempts. The behavioural features are synchronized with various physiological changes to ensure appropriate timing of sperm and eggs at the site of fertilization. The signs of oestrus are characteristic for each species.

Hormonal and neural control of female sexual behaviour

Oestrogens (oestradiol) are an absolute requirement in ensuring oestrus. They act on the **central nervous system** to elicit sexual behaviour, as well as stimulating the pre-ovulatory **luteinizing hormone** surge and, in turn, ovulation. There are some differences between species in that ewes and cows require progesterone prior to oestrogens to optimize their sexual behaviour, ovulation and other physiological events associated with successful copulation.

As in the male, some sexual reflexes in the female, such as **lordosis**, are organized by neural circuits in the spinal cord. The most important forebrain region controlling female sexual behaviour is the ventromedial nucleus of the **hypothalamus**. Its destruction abolishes copulatory behaviour and its stimulation facilitates the behaviour. Both oestradiol and progesterone exert their stimulatory effects on female sexual behaviour in this region: implantation of these two hormones directly into ventromedial nucleus of ovariectomized females reinstates both proceptive and receptive behaviour. Autoradiographical studies show that neurons in this region contain oestrogen and progesterone receptors.

Factors affecting female sexual behaviour

Low levels of sexual behaviour in females will result in problems with oestrus detection and sexual receptivity, and consequently depress reproductive success in both natural and artificial matings. As with the male, season, sexual stimulation

P.548

and sexual experience can affect the sexual behaviour of female farm animals. Sheep and cattle are seasonal breeders.

Sexual stimulation affects the sexual behaviour of females. In cattle, it appears that both natural matings and matings with vasectomized bulls reduce the duration of sexual receptivity or oestrus.

Exposure to unfamiliar females, regardless of their sexual status, hastens the onset of puberty in gilts. However, the effects on puberty attainment of exposure to unfamiliar females are relatively minor in comparison with the effects of boar contact.

The impact of male stimulation on sexual behaviour is well illustrated by the behavioural response of oestrous sows to boar stimulation. About 60% of oestrous sows will show either the immobility or standing response to firm hand pressure on their back in the absence of boars, but this can be increased to 90% by providing auditory and olfactory contact with boars, and further increased to 100% with the addition of visual and tactile contact with boars.

While it appears that male contact has an important role in stimulating the female's sexual behaviour, there are situations where continuous stimulation may adversely affect female sexual behaviour. Housing sows adjacent to boars, which allows continuous boar stimulation, over several weeks has been shown to create difficulties with oestrus detection, particularly in gilts or maiden sows. Habituation by females to the important boar stimuli (e.g. auditory and olfactory stimuli) that facilitate the standing response of the oestrous female may be responsible. Furthermore, prolonged boar stimulation at the time of detection may also reduce sexual receptivity. There are contradictory reports of the effects of exposure to rams during the non-breeding season on the onset of breeding activity in ewes.

Stress can affect sexual behaviour. Overcrowding of female pigs around the time of mating may depress their sexual behaviour. Stress during the follicular phase of the oestrous cycle is known to disrupt oestrous patterns and fertility.

The behaviour of domestic animals, including their sexual behaviour, is dependent upon a complex interaction between the organism's internal and external environment. The internal environment includes the central nervous system, the metabolic state of the organism and the endocrine milieu, while the external environment includes the organism's social, climatic and physical features. An understanding of the regulation of sexual behaviour is important in optimizing the reproductive performance and welfare of domestic animals.

Sexual selection

Sexual selection was identified by **Charles Darwin** as an explanation for the evolution of traits that appear to hinder survival (e.g. the tail of the peacock). It was traditionally considered as **selection** for traits that enhance mating success via direct male-male combat (**intrasexual selection**) or female choice (**intersexual selection**), but subsequently modified to

cover any traits that enhance **breeding** success, in order to include post-copulatory sexual selection for fertilizations, in the form of sperm competition and cryptic female choice, and post-zygotic sexual selection in the form of **infanticide**.

However, the distinction between the effects of natural and sexual selection are sometimes ambiguous, as survival may be considered a component part of an individual's life-history that has evolved to maximize lifetime reproductive success. Thus, sexual selection might be defined as: those natural selection forces that operate differently in males and females because of the strategies of the sexes. With this definition, sexual selection becomes a general term to describe selection acting differently in each sex, favouring adaptations that facilitate the sex-specific differentiation of phenotypes.

Shade-seeking behaviour

Providing shade is one of the primary methods used to protect livestock and outdoor captive animals from high heat load (direct solar radiation). The temperature can be up to 20°C lower in the shade than in the sun. In hot conditions black *Bos taurus* cattle can have rectal temperatures over 1°C lower (38.8 versus 40.1°C), and respiration rates some 50 breaths per minute lower (70 breaths per minute versus 130 breaths per minute) if they have access to shade. The **welfare** of animals is, in most cases, improved by the provision of shade, because it not only facilitates more effective temperature regulation and so reduces the risk of potentially fatal conditions such as heat exhaustion and heat stroke, but also reduces the risk of sunburn and certain forms of skin cancer, especially in animals with pale skin (notably Hereford **cattle** and **cats** with white ear tips). More effective body temperature regulation also improves productivity. However, shade may lead to a decrease in productivity if its use reduces the amount of time spent grazing, in the case of herbivores.

If natural shade or shade structures are not available, then animals exposed to hot climatic conditions may use whatever source of shade they can find. This may be shade cast by fence posts, water troughs and feed bunks - and even other animals. It is common to see hot cattle or **horses**, without access to shade, with their heads held low in the shadow of another. This behaviour may lead to other problems because bunching may decrease heat loss. Bunching is more common in dark-coated cattle than in white cattle, probably because they absorb more solar heat than white cattle. Temperatures on the poll of black cattle of up to 65°C have been recorded, and it has been observed that black cattle move to shade before white cattle.

Shade-seeking behaviour is not simply a function of ambient temperature. Related factors such as solar radiation levels (solar load), relative humidity, **stocking density**, microclimate under the shade (temperature and relative humidity), wind speed, the type of shade (e.g. natural, shade cloth or iron roof), time of eating and **genotype** will influence when an animal will seek shade and for how long it will use it. In some

P.549

circumstances animals may move out from under shade on extremely hot days if there is little air movement under the structure and/or the area is crowded. They may also leave shade to drink and eat; however, if space is limited they may restrict visits to water because of the risk of losing their space in the shade. Solar load plays a major role in shade usage; however, its importance has not been fully documented. Many animals will move out from under the shade as the sun sets, even when ambient conditions are still hot.

European (*Bos taurus*) breeds of cattle will start to seek shade when the ambient temperature exceeds a temperature threshold that typically lies between 20 and 27°C. At temperatures greater than 27°C, 70-100% of cattle will be under shade if it is available. The amount of time that *Bos taurus* cattle spend in shade increases by approximately 23 min/day for every 1°C increase in ambient temperature between 15 and 36°C. Above 36°C there will usually be 95-100% usage of shade.

The provision of shelter for captive animals should be considered essential. Natural shade in the form of trees, etc. is usually the first preference of many species, and trees have been shown to be particularly effective in relieving thermal radiation. The evaporation of water from the leaves of trees also cools the surrounding air, unlike purely physical shelters. Manmade shelters with a solid roof normally provide the highest level of protection and may be preferred, but the advantages of shade may be lost if the design of the structure is poor. For example, if the roof of the structure is low (e.g.

2 m rather than 5 m), the radiant heat from a galvanized metal roof may drive animals from the shade. Other common problems with artificial shelters concern the build-up of moisture from urine and faeces and a lack of air movement.

Shaping (operant)

Shaping (also known as successive approximation) describes the training process whereby differential **reinforcement** or **punishment** is used to encourage an animal to perform increasingly stringent approximations of a predetermined behaviour. It is typically undertaken using positive reinforcement, with any approximation initially reinforced and then only those responses that more closely resemble the goal reinforced in order to guide the form of the behaviour towards the end goal. For example, if we want a dog to sit quickly on command, we might start by rewarding any sit response to the command. Once this response has become reliable, i.e. the animal has learned the association between the command and sitting, we might only reward those responses that occur within a certain time following the command. In this way the animal learns that it has to sit more quickly for the reward. In practice, it is often helpful to focus on shaping only one aspect of the learned response at a time when trying to improve performance, i.e. the topography, latency, duration, frequency or error rate of the behaviour.

(DSM)

Shearing

Shearing, also known as clipping, refers to the practice of removing the fleece (wool) of an animal, typically a sheep but also some breeds of **goat** such as Angora. In the most primitive systems knives are used to remove the fleece from the animal, but more usually hand-shears (similar to heavy-duty scissors) and electric clippers are used, the latter predominating in the more developed areas of the world. The aim is not to remove all of the wool completely, but to leave the latest growth on the animal. Thus shearing is usually carried out when the fleece has 'started to rise', i.e. the tightly packed wool fibres move away from the skin, pushed up by the new wool growth. In temperate climates such as Northern Europe, south-eastern Australia and New Zealand, this occurs at the start of summer - after the last frost but before the hottest weather.

In recent times the predominant trend in developed countries has been a move to the use of contract shearing. Specialized teams of shearers and fleece-wrappers travel to farms as and when required, often shearing in Europe during early summer (May and June) and in the southern hemisphere during the European winter months, which is summertime in the southern hemisphere.

Experienced shearers maintain that the secret of shearing is to get the sheep in a comfortable position. Thus the animal is not struggling against the shearer and its **stress** levels are lower. One advantage of removing the fleece is that it decreases the risk of blowfly strike - the flies being attracted to the faecally soiled wool and laying their eggs there that hatch into maggots. Care of the animal is paramount when shearing. The skin must be kept tight at all times in order that no flaps develop that can easily be cut by mistake. Pulling the wool, however, is inadvisable, as this pulls the skin out into flaps, which means that a cut is almost certain. The fleece should be dry at shearing, as this aids cutting and helps to prevent mechanical clippers from becoming blocked.

(MM, HO)

Sheep

Sheep are animals belonging to the family Bovidae, subfamily Caprinae and genus *Ovis*.

Ovis

Sheep were one of the first species to be domesticated by humans, and archaeological data suggest that this process began in the Levant region of the Middle East and South-west Asia around 10,000 years ago. There is some doubt surrounding the wild origins of domesticated sheep (*Ovis aries*) and, until recently, it was believed that there were two separate groups of the wild mouflon, one in Europe (*Ovis musimon*) and one in Asia (*Ovis orientalis*) and that modern domestic breeds had largely developed from the European mouflon. However, the European mouflon is now considered to be a relic of the first domestic sheep that were brought into Europe by migrating groups of people, rather than the remnants of a separate species.

As newly migrated communities settled in different regions the sheep they had taken with them became isolated from other groups of sheep and they began to develop characteristics peculiar to their region. Distinct breeds emerged, often taking their name from the geographical area in which they

P.550

developed. Sheep provided these early farmers with meat, wool, skins and milk, and humans have since continued to harvest these products, although geographical region and the economic climate determine how each of these commodities is valued.

During the Mediaeval period sheeps' wool was extremely valuable as the principal cloth material, and England (in particular, the great monasteries) gained great wealth by exporting wool to Europe. Some counties of England profited enormously from the wool trade, and this was largely determined by the type and quality of the fleece produced by the local sheep. For example, the Ryeland sheep of Herefordshire, which derived its name from the vast areas of rye grass grown in that county, produced the finest wool in the British Isles, fetching such high prices that it became known as 'lemster-ore' (referring to an area of Herefordshire known today as Leominster). The county of Lincolnshire was also well established as a wool-producing area by the 13th century, and its importance continued throughout the Middle Ages and up to the Industrial Revolution. The large-framed Lincoln Longwool sheep were kept on the rich grass of the Lincoln Fens and produced four to five times as much fleece as the Ryeland. The coarse Lincoln wool was exported in considerable quantities to neighbouring European countries, making Lincoln one of the richest cities of Mediaeval Britain.

As the cotton trade grew, wool was replaced as the preferred material for clothing and meat, or mutton, became the primary commodity, helping to sustain the growing urban populations during the Industrial Revolution. During this transitional period farmers, such as the pioneer Robert Bakewell, began to practise artificial **selection**, a process where animals were selectively bred for specific attributes and which allowed for the development of specialist breeds designed to maximize production of one commodity, i.e. either wool, meat or milk. The selection for economically important traits was highly successful and, in a few generations, lambs could be fattened to slaughter weight up to 12 months earlier than previously.

Worldwide there are now over 200 distinct **breeds** of sheep, of which 70 are British and, even today, the influence of British sheep breeds is considerable throughout the world. Many countries now farm sheep that are descended from British stock, the most notable exception being the fine-woolled Spanish Merino that is the favoured breed in Australia. More recently, breeds such as the Dutch Texel and the French Charolais and Rouge de l'Ouest have also become popular, particularly for crossing with cross-bred ewes to produce robust, fast-maturing lambs.

Milk sheep can be found in many European countries, including Greece, Italy and Turkey, as well as the Middle East and Saudi Arabia. There are around 25 different dairy sheep breeds, including Assaf, Friesland and British Milkshope, although any animal that has a placid temperament and can rear twins or triplets would be suitable. Sheep milk is particularly high in solids and is used for making cheese, yoghurt and butter. The fat in sheep milk also contains a high level of medium-chain triglycerides (MCT), which are highly beneficial to humans both medically, by inhibiting cholesterol deposition, and nutritionally. Sheep milk is used to feed premature human infants, as well as providing a source of dairy products for those people unable to digest cow's milk.

The genus *Ovis* is characterized by the presence of small glands in the groin area and the tear duct, as well as interdigital glands. These glands all secrete a clear fluid, which gives sheep a characteristic scent. The size, shape and colour patterns of domestic sheep vary considerably between breeds, though most domestic breeds are now principally black and/or white, with a few older-type breeds of a reddish (tanay or moorit) colour. Modern domestic sheep also have long tails, are no longer able to shed their fleece and the female (ewe) is generally smaller than the male (ram). The presence of horns in

males and females differs between breeds. For example, both genders of the Swaledale breed are horned, whereas the Herdwick ram is horned but the ewe is polled. Both genders of the Kerry Hill breed are polled.

Ovis aries

Ovis aries breeds on a seasonal basis and, although rams are capable of mating all year round, their **libido** is diminished and semen is of poorer quality outside the **breeding** season. Ewes are most fertile during September, October and November in the northern hemisphere, because their **oestrus** cycle is triggered by a decrease in the amount of daylight. Sheep are, therefore, classed as short-day breeders. A ewe is seasonally polyoestrus, so will continue to cycle every 15-17 days for an average of 30 h, either until mating is successful or to the end of the season (the anoestrus period). Breeds such as the Mouflon that originate from areas closer to the equator, where there is less variation in seasonal temperature, have a longer breeding season. Onset of oestrus can be artificially synchronized in a flock with the use of intravaginal sponges containing either **prostaglandin** to induce oestrus or progestagen to prolong the length of an oestrus cycle. Artificial synchronization of oestrus allows greater control over lambing dates and shortens the lambing period.

During oestrus the ewe is more restless and tends to bleat more frequently. To detect oestrus the ram smells the ewe's urine, using both smell and taste, showing the '**flehmen** response' of curling his upper lip and raising his head. The ewe reciprocates by smelling the body and genital area of the ram and the pair begin to circle each other. The ram then faces the rear end of the ewe, licking her genitalia and nudging her while grunting. If the ewe is ready to mate she will adopt a characteristic position (**lordosis**) that enables the male to mount, and copulation takes place.

Embryonic implantation occurs approximately 23 days after fertilization and the **gestation** period lasts for approximately 148 days, when ewes produce lambs to coincide with the warmer weather and rich spring grass. Prolificacy varies between breeds, with those from harsher climates tending to produce fewer lambs than breeds from milder climates. Some breeds such as the Finnsheep can produce up to five lambs, although single or twin lambs are preferred as the ewe can generally raise one or two offspring with little or no intervention. The birthweight of a lamb can be affected by litter size, sex, the age and breed of its dam, along with the level of nutrition, particularly during the latter stages of pregnancy.

Optimum flock health is maintained by breeding from healthy sheep of good conformation and ensuring that ewes have a full set of teeth to optimize grass intake. Lambs are

P.551

born with a set of eight milk incisors, which are replaced with permanent incisors at the rate of two each year so that a set of eight mature incisors would mean a minimum age of 4 years, and the sheep would then be said to be 'full-mouthed'. The teeth gradually spread as the sheep ages, and either fall out or break off. When this occurs, a sheep is said to be 'brokenmouthed' and, as it becomes increasingly difficult to ingest sufficient grass to maintain body condition, affected individuals are culled from the flock. Ensuring that fluctuations in nutritional requirements are met throughout the different stages of the **reproduction** cycle is vital when maintaining a healthy flock.

There are four major production stages: breeding (30-45 days), late gestation (30-45 days), **lactation** (30-45 days) and maintenance (210-240 days, the latter including the first 100 days of gestation). At each of the four phases the diet should provide sufficient nutrients for the maintenance of the ewe and lamb, both before **parturition** and up to **weaning**. In general terms, maintenance should be achieved if a ewe consumes 3% of its own body weight daily during the breeding phase and late gestation phases, 4% during lactation and 2% during the maintenance phase. An increase in the level of nutrition at mating time increases the likelihood of twins, a practice known as 'flushing'.

Requirements for specific nutrients also fluctuate between the four phases. During the late gestation phase the fetal lamb has a high requirement for carbohydrate and is able to maintain its own blood sugar concentration at the expense of the dam's. Too little carbohydrate can cause pregnancy toxemia in the ewe, resulting in neurological dysfunction. This is often termed 'twin lamb disease', as it is more likely to occur when a ewe is carrying two or more lambs. Nutritional requirements for calcium, phosphorus and water increase markedly during the lactation phase, to ensure adequate milk supply for growing lambs.

A copper deficiency during late gestation inhibits nerve development and limb coordination in the lamb, causing a condition known as 'swayback'. Copper metabolism is different in sheep to other farmed species because it is not excreted very efficiently from the liver, which acts as the main storage organ. Excessive intake of copper will result in copper toxicosis, where the liver becomes saturated and damaged. Copper is then released into the bloodstream, killing off red blood cells, and the condition is fatal if left untreated. Copper also plays an important role in the natural pigmentation of hair and wool

and in the crimp of wool. A copper-deficient fleece will have reduced elasticity and affinity for dye, reducing both its thermal and water-shedding properties for the sheep and affecting its value as a commodity.

Non-nutritional **diseases** to which sheep are susceptible include scrapie, **footrot**, **fly strike**, bluetongue and orf. Orf is a viral infection that causes severe blistering and scabbing around the muzzle and lower leg, and can be prevented through vaccination. Bluetongue is also a viral infection, which is transmitted by *Culicoides* spp. (midges), and can again be prevented through vaccination. Bluetongue causes fever, lameness, abortion, emaciation and can end in **death**, though the mortality rate is around 10%. Ulceration of the mouth with a swollen, cyanotic tongue gives the disease its name. Scrapie is a degenerative disease of the **brain** caused by a form of protein known as a prion, and is untreatable. Footrot is the most common disease in sheep, and is caused by bacteria found in the soil and faeces. When conditions are moist and warm, bacteria thrive and colonize the join between the hooves, from where they penetrate the skin. Symptoms of footrot include poor growth, cracked hooves, lameness and necrosis of the tissue beneath the horn, causing a foul smell. Vaccination can help prevent footrot, along with regular hoof trimming and the use of foot baths with antiseptic agents.

Fly strike is a particular problem in warm, muggy weather, when the green-bottle fly lays its eggs in the wool around the tail region. When hatched, the maggots feed on skin and flesh. Sheep with dirty hindquarters are particularly susceptible to fly strike, and prevention includes control of scouring, keeping the hindquarters clean and dry by cutting away any dirty fleece (dagging) and tail-docking of lambs (**see: Docking - tail**) to reduce the likelihood of dags forming. In countries such as Australia the prevention of fly strike through dagging is more difficult, as sheep roam over extensive areas of land and are both harder to identify and catch for treatment. The traditional method of controlling this disease was to remove the skin from around the perianal region of lambs (**mulesing**), and the resulting scar tissue helped to form a barrier against maggot infestation.

Although sheep are largely managed in extensive farming systems, a number of welfare problems relating to **confinement** occur, especially during **transport**, which can be over enormous distances as live export is preferred by some countries to coincide with religious festivals.

The British sheep industry has a stratified breeding system that incorporates both pure-bred and cross-bred sheep adapted to different regional environments, which perhaps explains the diversity of breed that still exists in this nation. Hardy hill sheep such as the Welsh Mountain, the Scottish Blackface and Swaledale are kept on poor-quality hill grazing for the first four breeding seasons, when they produce pure-bred lambs for flock replacement. For the fifth breeding season the ewes are brought off the hills to milder conditions on upland farms (a process that is known as 'drafting', and the ewes called 'draft ewes'). Here they are crossed with upland breeds, such as the Bluefaced Leicester or Border Leicester, to produce strong, prolific and hardy ewes for commercial flocks. There are about 12 recognized crosses, including the Mule, a Bluefaced Leicester ram crossed with a Swaledale ewe.

Many of these cross-bred, or half-bred, ewes produced on upland farms are sold on to lowland farms, where they are then crossed with a lowland meat breed such as the Suffolk or Texel to produce meat lambs. A ram that is crossed with a half-bred to produce meat lambs is known as a 'terminal sire'. Cross-bred ewes tend to mature early and can be bred from in their first year. They generally produce twin lambs and make good mothers.

Once a lamb is born the dam will lick it thoroughly clean and dry, and it is during this phase that the bond between a lamb and its dam is developed, initially using olfactory cues (**see: Maternal behaviour**). As the lamb and ewe begin to recognize each other, visual cues become increasingly important in reuniting them as the lamb grows and strays further afield. As a lamb develops and becomes more nutritionally independent, the ewe will initiate the weaning

P.552

process by refusing to stand or butting the lamb away if suckling is attempted.

Flocking behaviour in sheep is a strong anti-predator response that can cause confusion in a potential predator, which is then unable to focus on one animal as a target. A flock continually assesses its environment, not only by looking out for potential predators but also by watching each other (**see: Vigilance**). Each individual tends to graze with at least two other flock members within view, enabling a whole flock to react very quickly should one animal respond to any perceived threats. An alarmed sheep will hold its head up and walk forward with rapid, but short, steps. A ewe with young lambs is more likely to stand her ground for longer against potential predators, stamping the ground with one front foot. The tendency for sheep to flock together when confronted allows farmers to handle and move large groups over extensive areas with relative ease, particularly when trained sheepdogs are used.

Sign

An objectively measurable phenomenon that is associated with a particular condition to such an extent that it is indicative of its presence. A sign must be able to be observed by someone other than the patient (i.e. not something about which the patient complains but cannot be observed - a **symptom**). In animals one can deal only with what is observable, and therefore all evidence of conditions are signs. For example, excessive barking can be a sign of **separation anxiety**; a high rectal temperature may be a sign of infection.

Signal

Signals are a major component of animal **communication** - behaviour that is integral to the most important aspects of their lives. The other major components are the animal producing the signal (variously referred to as the signaller, sender, actor or generator) and the animals perceiving the signal (receivers, reactors or detectors). Signals are best thought of as the specialized information carriers linking communicating animals (i.e. signallers and receivers) in a communication network. Signals can be defined as adaptations to transfer information. This biological definition is close to the everyday use of the term signal as something that is intended to convey information. While signals always contain information, not everything containing information is a signal. This important distinction is illustrated by the difference between a weathervane and trees swaying in the breeze. The weathervane is designed to show wind direction and has specializations to achieve this, such as an easily interpreted direction indicator (the vane) and letters indicating the cardinal compass points. On the other hand, trees bend because of the force of wind and, in doing so, they incidentally give relatively imprecise information on wind direction; they do not show any specializations to indicate direction.

While signals are a diagnostic characteristic of animal communication (so much so that communication is sometimes defined as behaviour involving signals), they are only one source of information available to animals. However, signals' roles as specialized information carriers and the nature of communication mean that such information is more complex, more diverse and possibly more important than information from other sources.

Indeed, diversity is a striking characteristic of animal signals. Part of this diversity is explained by signals that use the different sensory capabilities of receivers. The term signal modality (or channel) refers to the sense used to detect the signal; for example, animals see visual signals and hear acoustic signals. Multimodal signals require two or more of the receiver's senses. There are six signal modalities:

- *Visual signals* most commonly use reflected light (although some species can generate light for signalling) and often involve movement (such as the display of brightly coloured plumage).
- *Acoustic signals* transmit information through pressure differences in the transmission medium (i.e. air or water). In regions very close to the signaller, termed the near field, information is transmitted by displacement of the transmission medium.
- *Vibrational signals* (or seismic signals) transmit information through vibrations in the substrate.
- *Chemical signals* are detected by the sense of smell/taste. They differ from other signal modalities in that signals such as scent marks are deposited (and persist) on the ground or vegetation and can be approached by the receiver, often several days after the signaller produced the signal (**see: Chemical communication**).
- *Tactile signals* transmit information through the sense of touch, and therefore the signaller and receiver must be in physical contact.
- *Electrical signals* are used by two groups of freshwater fishes (South American gymnotids and African mormyrids) that have an electrical sense and specializations of muscle or nervous tissue to generate electrical signals (**see: Electric field**).

Each of these six modalities differs in transmission speed, persistence, inherent directionality and the effect of obstacles. These characteristics influence signal form and how signals are affected by the transmission environment, thereby contributing to signal diversity. Another aspect that increases signal diversity is that animals often produce graded signals, in which signals vary in form as factors such as **arousal** and **motivation** change.

Conflicts of interests between signallers and receivers generate considerable signal diversity. Such conflicts arise because it is rare for information transmission to mutually benefit both signaller and receiver. This asymmetry in pay-off can help to explain otherwise puzzling features of signals such as differences in signal conspicuousness (less conspicuous signals if the pay-off asymmetry is small and more conspicuous signals if the asymmetry is large). Conflicts of interest and the realization that signallers and receivers exert a selection pressure on each other (resulting in co-evolution and arms races) are central to evolutionary explanations of signal features.

A closely related question is whether signals are honest. When potential prey are signalling to deter predators from attacking, or females are using male signals to choose the best mate, we might expect selection to favour signals that best achieve signallers' interests (even at the expense of receivers), that is, signals are unlikely to be honest. However, we would

P.553

also expect selection to favour receivers that are adept at extracting the information that best furthers their survival and reproduction. This co-evolutionary arms race between signaller 'salesmanship' and receiver 'sales resistance' is most likely to result in signals that are 'honest on average'.

Another factor that contributes to signal diversity is that signals may be graded. That is, the form of the signal varies with internal factors such as motivation.

Signals can originate in two ways - through either ritualization or sensory exploitation. Signals originate by ritualization through **selection** for increased efficiency of information transfer, so that a behaviour (termed the signal precursor) that contained some information becomes specialized to transmit that information - through exaggeration, repetition, simplification and increased stereotypy. Many signal precursors fall into one of three categories: (i) intention movements that contain information on what the animal is likely to do next; (ii) autonomic responses (often involuntary) that change the body's state; and (iii) displacement activities that often indicate motivational conflict. By contrast, signals originate by sensory exploitation through selection to exploit receivers' 'pre-existing sensory biases'. For example, signals used in mate attraction may be selected to contain features to which the receiver is already sensitive in a different context, such as prey detection.

The question of whether signals contain honest information has been a major focus of research on communication, particularly in relation to mate choice, resource defence and predator-prey interactions. A rather risky example is the use by male spiders of signals for mate attraction that stimulate females' prey detection receptors.

Singer, Peter

Australian philosopher Peter Singer (b. 1946) is presently Ira DeCamp Professor of Bioethics, University Center for Human Values at Princeton University, New Jersey. Singer is also co-founder of the Centre for Bioethics at Monash University, Victoria, Australia. He is a prolific philosopher and has written on biomedical **ethics**, moral theory, human rights and the ethics of globalization. Singer's *Animal Liberation* (1975) is often credited with thrusting concern for treatment of animals used in agriculture and research into mainstream discourse. *Animal Liberation* gave philosophical teeth to other contemporaneous works, most notably, **Ruth Harrison's** *Animal Machines* (1964) and Stanley Godlovitch *et al.*'s *Animals, Men and Morals* (1972). *Animal Liberation* inspired and spawned a generation of philosophically savvy animal protectionists and **animal rights** advocates (broadly speaking).

Singer's championing of animal protection or animal rights (in a broad sense) is underscored by his commitment to **utilitarianism**. Singer's brand of utilitarianism is *preference utilitarianism*. Unlike hedonistic utilitarianism, which focuses on maximizing happiness or minimizing unhappiness as to what is intrinsically valuable, Singer takes satisfaction of preferences and interests (and their frustration) as constitutive of what is valuable (Singer, 1979a). For Singer, morality requires that we maximize preference satisfaction (including consciously pursuing desires and projects and goals) or minimize preference frustration.

Singer begins with the view that an animal's ability to experience **pain** and pleasure, i.e. **sentience**, is an interest-making property, and should be the basis of our ethical assessment of our treatment of animals. He contends that, '[t]here can be no moral justification for regarding the pain (or pleasure) that animals feel as less important than the same amount of pain (or pleasure) felt by humans' (Singer, 1990). Elsewhere, he argues that '[a]s long as a sentient being is conscious, it has an interest in experiencing as much pleasure and as little pain as possible. Sentience suffices to place a being within the sphere of equal consideration [of like] interests' (Singer, 1979b). On his **preference**-based analysis of what is intrinsically valuable, Singer contends that animals that can conceive of their own futures and have the capacity for forward-looking desire satisfaction are harmed morally when they are not allowed to exercise their preferences.

According to Singer, sentient animals are *sufficiently* like us in morally relevant ways - they have desires, preferences about their future and can experience pain and pleasure. He undermines the weight given to human **language** and rationality by contending that 'pain is pain', no matter the identity of the experiencing subject, and that equal consideration of similar interests does not hinge on seemingly unique human qualities. The combination of the ideal of interspecific equality, coupled with the sentience criteria and his brand of utilitarianism, and the fact that large scale animal farms and research facilities allegedly are bound to cause immense suffering, leads him to the conclusion that we should boycott these industries. Singer concludes that we ought to become moral vegetarians and we should cease unnecessary use of animals in medical research, since the overall benefit to humans and animals does not justify the harm done to animals (Singer, 1975, 1990).

Singer's prescription for moral vegetarianism is not based on the thesis that killing certain animals is wrong in itself. Since Singer is committed to utilitarianism, his objections to killing emphasize the gross harmful effects that killing animals has on reducing the amount of preference for a pleasant life. If husbandry conditions are improved such that the preference for a pleasant life is maximized, then Singer's utilitarian calculus might produce a different conclusion to the moral obligation to be vegetarian. Singer's approach as discussed here is consistent with efforts to *reform*, not eradicate the various industries of animal use.

In terms of reform, an effective strategy in some cases has been to boycott industries of animal use, for example

P.554

commercial animal agriculture. However, if removing oneself from the decision-making process minimizes utility, then reform may be better brokered through active participation in public policy formation or conscientious consumerism. Because the utilitarian calculus is contingent on shifting empirical facts, **vigilance** as regards structural changes and improvements in animal **welfare** on an ongoing basis should be observed in order to promote the best possible balance of benefits over harms for all considered.

Singer has helped to popularize two concepts that get used as fuel in the animal liberation debate. The first, '**speciesism**', coined by **Richard Ryder** (1970, privately printed leaflet), criticizes discrimination against animals (or privileging human interests) *simply* on the grounds of species identity. If we lack a morally relevant difference for being partial to human interests, then we should abandon species boundaries as a way of excluding animals from the moral community; otherwise, we embrace an indefensible form of prejudice akin to racism or sexism (Singer, 1979a).

Singer also made famous the 'argument from marginal cases'. Exemplifying the virtues of logical consistency, the argument contends that we must provide a morally relevant difference to justify differential treatment of animals and human beings. However, the qualities that are often given, such as rational agency, language, self-awareness and self-governance, fail to

apply to all and only human beings. 'Marginal' human beings - for example, profoundly mentally disabled individuals such as those with hydrocephaly, Tay-Sachs or anencephalic newborns - may not have these above-mentioned qualities and may never demonstrate them. If the permissibility of animal agriculture or animal research is justified on the basis of the former qualities, then we would justify using 'marginal' humans.

Fellow utilitarian Raymond Frey holds that, because the value of a life is a function of its quality, and its quality corresponds to the enrichment opportunities open to the subject, Singer's argument does not go far enough with respect to equal consideration. Frey is less hesitant than Singer about using marginal human beings to promote the overall good of other beings, in place of non-defective adult animals.

Skinner, Burrhus Frederic (Fred)

Burrhus Skinner (1904-1990) was one of the early champions of behaviourism and the experimental laboratory approach to psychology and learning (referring to the mind as a 'mysterious and dangerous metaphor'). His enthusiastic work on **instrumental conditioning** has led many to refer to it as Skinnerian learning, in recognition of his enormous contribution to the field. This includes the development of a controlled experimental environment that allows the automatic recording of the behaviour of animals in response to different contingencies, and which bears his name (Skinner box). An additional possible reason why Skinner achieved such notoriety within the discipline relates to his philosophical skill and appreciation of its global influence. He was not afraid to challenge conventional thinking in relation to the implication of his work and was quoted as saying 'All human beings are controlled, but the ideal of behaviourism is to eliminate coercion, to apply controls by changing the environment in such a way as to reinforce the kind of behaviour that benefits everyone'.

Although some of his work was sponsored by the military, Skinner objected to the harm caused by war. He believed that behaviour should be shaped with positive **reinforcement**, and often rejected the use of **punishment**. Although some Skinner boxes have electrified floors for delivering **aversives**, this was not a focus of his work, and others were more willing to use much more powerful currents than he, challenging his results that punishment had only temporary suppressive effects on behaviour.

Skinner originally aspired to be an author and poet before turning to a career in psychology, and published one notable piece of popular fiction, *Walden Two*, a story about a community living a Utopian existence according to behaviourist principles, which challenges many of the principles conventionally associated with a free society. The book has sold over 1 million copies globally.

Slats

Slats are made from a number of parallel beams (slats) with gaps or slots in between. They are used for floors in cattle, pig and sheep **housing**, so that faeces and urine can fall between the slats into a pit, without the floor having to be cleaned. A high **stocking density** of animals is often required so that the animals tread the excreta through the slots. Slats may be made from concrete, wood or plastic. Poorly constructed slatted floors cause animals to walk with their heads down, fixing their gaze on the floor ahead of them. This enables them to position their hooves carefully; there is less walking activity in total and it is slower than if the animals are on solid floors. Animals may even spend less time grooming their hindquarters because of the risk or fear of overbalancing.

However, well-designed slatted floors allow animals to be kept at high stocking densities without bedding and to remain reasonably clean. If slats are too narrow, there is an unacceptable strain on them, particularly if they are very long; but, if they are too wide, there is inadequate disposal of faeces between the slats. Optimum slat width is about 150 mm for cattle, and the slats should be T-shaped in end-on profile to encourage dung to fall into the pit below. The gaps between the slats should be about 40 mm wide. If they are less than this the faeces do not pass through easily. Great care should be taken that slats have been manufactured from high-grade materials to the required loadings for the class of stock to be kept on them, including the necessary reinforcement.

P.555

Slaughter

In comparison with killing an animal for sport or pest control or the humane destruction of **companion animals**, the process of slaughtering an animal for meat is constrained by requirements for food safety, in terms of minimizing food contamination and drug use, and economical considerations. Consumers demand cheap meat, which drives producers to develop faster and more cost-effective production systems.

Animal slaughter for meat is almost always conducted in a **slaughterhouse**. To slaughter an animal is to cause **death** by loss of blood; sticking is the act of making an incision into an animal to allow bleeding. In the European Union (EU) all animals are required, under Directive 93/119, to be stunned prior to slaughter. Under this Directive, Article 3 requires that no animal should be caused or permitted to sustain any avoidable excitement, **pain** or **suffering** during **restraint**, **stunning**, slaughter or killing. There is a derogation for **religious slaughter**. Equivalent legislation or guidelines have been passed in most developed countries, including the US Code of Regulations Title 9, Chapter 3, Part 313 Humane Slaughter of Livestock, the Canadian Meat Inspection Act and the Australian NACCAW guidelines on The Welfare of Animals at Abattoirs 1994 (as amended).

To stun an animal is to render it unconscious and insensible to external stimuli of any sort. The principal welfare issues arising from the stunning and slaughter of animals for food relate to:

- **fear** and **distress** due to poor pre-slaughter **handling**;
- severe pain, fear and distress due to failure to stun; and
- severe pain, fear and distress due to recovery of sensibility prior to death during bleeding.

Although all of these problems may occur during the slaughter of any animal, specific welfare issues tend to be associated with particular handling, stunning and killing systems and to certain species. Many handling, stunning and slaughter systems that worked well and with minimal welfare problems, when throughput was low and labour plentiful, have inherent problems at higher throughput speeds or where tasks are automated. Some welfare problems specific to certain commonly used systems and to species commonly slaughtered for meat are examined in some detail below. The methods used to monitor each problem and actions which may be taken to address it are then discussed.

Fig. S.1. The use of electric goads is often necessary when loading animals into controlled-atmosphere stunners.

Fear and distress due to pre-slaughter handling

Cattle, sheep and pigs

Injury, pain, fear and distress may arise in poorly designed premises and handling systems for cattle, **sheep** and **pigs**. The mixing of different groups of animals from different farms or pens on arrival at the **lairage**, the pre-slaughter holding area, may cause fighting, resulting in fear and injury. This is a particular problem for pigs and uncastrated male cattle. Hot or humid lairage conditions may cause discomfort in ruminants, but **heat stress** is a particular problem for pigs, which have a narrow thermoneutral zone and are less able to control their body temperature. In pre-slaughter handling systems, including unloading ramps and **raceways**, animals may be reluctant to move forward due to noise, draughts, poorly positioned personnel, or poorly designed races with right-angled turns and open sides. This may result in lairage personnel beating, prodding or dragging animals, or twisting sensitive parts of their anatomy in order to persuade them to move forward, especially where throughput speeds are high. At some premises, electric goads are routinely used for unloading and moving pigs through the lairage and into stunning pens or gas-stunning equipment.

Of particular note are high-throughput pig slaughterhouses where, typically, approximately 600 pigs may be killed per hour, through 90% carbon dioxide stunner/killers. For controlled-atmosphere stunning, pigs are loaded into suspended cages, or gondolas, and lowered into pits full of carbon dioxide. Carbon dioxide is very **aversive** to animals, and required throughput rates for some stunners that are currently widely in use may be achieved only by using teams of lairage personnel equipped with electric goads. The use of a **goad** to load a gas stunner is illustrated in Fig. S.1.

Driving practices may be monitored by routine recording of the number of carcasses affected by bruising and stick marks and the extent of the lesions; stick marks in cattle are shown in Fig. S.2.

There are a number of systems available for the assessment of carcass damage in pigs. Such systems use a point-scoring

P.556

system, usually from 1 to 4 or 5, to record the extent of damage in a number of defined areas of the carcass, usually four or five areas. The sum of scores may then be used to compare damage between carcasses. A sample of several carcasses from each herd killed allows comparison of handling between herds. However, this will give a measure of overall damage, including damage to animals on the farm and during loading. Handling in the lairage may be assessed by routine measures of the frequency of goad use, beatings, tail twisting, animals slipping or falling, vocalization, etc. in a given time period.

Fig. S.2. Stick bruising on cattle carcasses due to poor pre-slaughter handling.

The cumulative amount of pre-slaughter handling stress may be roughly estimated by measuring the pH of carcasses. When animals experience high levels of **stress** during fasting and loading on the farm, in **transport** and in handling in the lairage, their carcasses may have either low pH, causing pale, soft, exudative (**PSE**) **meat** or high pH, causing dry, firm, dark (**DFD**) meat. pH meters are available, but must be used at specific anatomical locations on the carcass and at specific times post-slaughter in order to allow valid comparison between both carcasses and slaughterhouses.

Fighting in the lairage may be avoided by preventing the practice of mixing animals on arrival. Extension of lairage area or reduction in throughput rate may be considered if mixing of groups occurs frequently (see Fig. S.3.).

Heat stress may be avoided by installation of suitable ventilation systems in the lairage. Sprinkler systems for pigs may reduce the chance of heat stress and will also reduce fighting. However, sprinkler systems may increase the risk of heat stress through increasing humidity in very hot weather, and may cause **cold stress** when used to prevent fighting in cold weather. Pigs suffering from cold stress are clearly identified, as they shiver. Temperature, relative humidity and ammonia levels may be continuously monitored in the lairage, and action may be taken to reduce them when excessive. As a guide, temperature of over approximately 26°C and a relative humidity of roughly >90% are likely to cause problems for pigs, although higher temperatures are tolerated where relative humidity is low. Levels of ammonia of over 25 ppm are aversive.

An adequate supply of clean water should be available at all times to all lairaged animals. There should be a sufficient number of drinkers or troughs, in good working order and at animal height, in each lairage pen. Pressure on throughput may cause overstocking of pens or inappropriate classes of livestock to be held in them, with the result that the drinker:animal ratio may be too small or drinkers may be at an inappropriate height. Poor lairage management, due to poor personnel training or overstretch, may result in non-serviceable drinkers.

Fig. S.3. Pigs fighting in the lairage.

Pre-slaughter handling problems may be prevented by improving unloading facilities and raceways to eliminate steep ramps (those over 20°), slippery floors, sharp corners, noises caused by machinery or lairage personnel, open-sided raceways and those going from light to dark areas. Scientific research, which includes a considerable body of work by Temple Grandin based in the USA and Canada (see Further reading, below), has identified a number of problem areas in this respect. In practice, problem areas may be identified by observation of animals being moved through the lairage to identify locations at which animals refuse to move forward, which physical coercion is routinely used, where animals slip or where there is excessive vocalization.

Expert advice may be sought when designing the layout of, and materials used in, new lairage facilities or when existing facilities are being extended, in order to ensure that they cause minimal welfare problems during unloading and pre-slaughter handling. In many countries cattle must be identified at the slaughter plant for the purpose of disease control, including that for new variant Creutzfeldt-Jakob disease. This causes additional stress if restraint is required in order to read ear tags. Electronic systems of identification may help to avoid this additional stressor.

Poultry: broiler chickens, end-of-lay hens, turkeys and ducks

All poultry are 'harvested', either manually or by machine, into crates that may be stacked into a module. Heat stress frequently causes severe discomfort, distress and death in hot weather. This is a particular problem for meat birds, due to their high metabolic rate and narrow thermoneutral zone and to the high stocking densities at which they are transported. Hens may suffer from cold stress in cold weather due to poor **feather** cover at the end of lay.

At the plant, birds are removed from the crates, either manually or by tipping on to a conveyer belt, and inverted to be placed in shackles, i.e. metal frames shaped to allow the legs to be slotted downwards into them to secure the bird on the kill line. This causes fear and distress, and frequently pain, which arise from the handling and shackling of birds with leg

P.557

disease or fractured bones, from which conditions poultry frequently suffer. Typical line speeds of up to 200 birds/min for broilers and 50 birds/min for **turkeys** make speed of shackling imperative and so preclude careful handling.

Heat stress in the lairage may be monitored by estimating the proportion of birds that are panting. The problem may be addressed by reducing the **stocking density** of birds in the crates, careful planning of 'harvesting' and journey to the plant to reduce lairage times and, if necessary, installation of fans in the lairage.

Pain at shackling is inevitable in plants using water bath stunners. However, levels of excitement may be reduced by using blue light in live bird areas, installing breast comforters on the line and reducing noise, draughts and personnel in live bird areas. Scientific research has shown that blue light has a calming effect on poultry, and a breast comforter, consisting of a continuous rubber strip fixed at breast level along the kill line, prevents the bird from swinging and so reduces distress. Sharp bends in the line cause birds to flap and are therefore usually avoided at the plant design stage. The use of controlled-atmosphere stunners avoids the need to shackle live birds.

However, there is some controversy over current, commercially available gas stunners that use carbon dioxide, which is aversive to birds but is inexpensive and produces good carcass quality. The alternatives include inert gases, such as argon, which are not detectable by the birds. However, inert gases may be more expensive and cause anoxic convulsions, which may be aesthetically unpleasant to operatives and give poor carcass quality due to blood splash.

Severe pain and fear due to failure to stun or recovery of sensibility

Cattle, sheep and pigs

Cattle are most commonly stunned through use of a **captive bolt** stunner, as illustrated in Fig. S.4, which disrupts the brain structure by accelerating the brain against the skull.

The positioning of the stunner is critical and requires considerable skill. UK slaughterhouses generally use cartridge stunners, while in the USA hydraulic instruments are commonly employed. Re-stun rates may be up to 5% for hydraulic stunners but are lower for cartridge instruments. The effectiveness of head restraints to aid stunner positioning is controversial. An electrical stunning box is available for cattle, widely used in Australasia. There is some debate concerning the effectiveness of electrical stun boxes for cattle. The electrical stun box delivers a head stun, which causes immediate insensibility, followed by a nose to heart stun that stops the heart, eventually leading to death, and finally a spinal depolarization to reduce convulsions and protect the slaughterman. The final depolarization may mask signs of an effective stun. The boxes involve complex electric and computer systems, which must be serviced by only trained personnel. The currently available box does not incorporate instrumentation indicating currents applied under load. Dirty cattle or electrodes or inadequate water supply to electrodes will impair the effectiveness of stun.

While captive bolt stunners usually kill an animal outright, cattle may recover from an electric stun where there is an inadequate heart stun; stun to stick time is therefore critical, and should be less than 40 s to ensure that a stunned animal does not recover sensibility. Clonic convulsions, i.e. rapid, repeated and uncontrolled paddling limb movements, occur in animals for which there is inadequate spinal depolarization, which may delay sticking.

Sheep are stunned by a head-only electrical stun, using a hand-held electrical stunner, or by captive bolt stunner. Many sheep stunned using an electrical stunner show signs of recovery of sensibility on the bleed line, i.e. that part of the kill line incorporated to allow the legally required, minimum duration of bleeding before further dressing of the carcass may begin. The maximum voltage applied by hand-held stunners is limited due to health and safety considerations, and there may be variation in electrical impedance of sheep heads, due to either wool on the head for some breeds or extensive skin contamination from muddy conditions in the field or during transport.

There exists, therefore, a risk that insufficient current may be delivered, causing inadequate stunning. Sheep are usually stunned while manually restrained, with the resultant possibility that positioning of stunning tongs may be poor, leading to failure of stunning. Stunning for 3 s, at a constant voltage of 250 V, has been shown to produce an adequate stun if tongs are correctly positioned.

Pigs may be stunned using either a hand-held electrical stunner, to give a head-only stun, an automatic stunner that applies both a head and heart stun, or a controlled-atmosphere stunner, usually carbon dioxide. Where head-only stunning is used, the duration of application of the head electrodes is critical; this should be 3 s for high-voltage units and 7 s for low-voltage stunners. The stun to stick time for these pigs should be less than 15 s, to ensure loss of sensibility until death. The positioning of head tongs is critical, and should be immediately below the ears to ensure that the shock is applied across the brain. Poor positioning of head tongs or poor electrode contact may cause some pigs to be non-stunned or to show signs of recovery on the bleed line. Signs of recovery in pigs after carbon dioxide stunning may be due to inadequate duration of exposure to the gas, air pockets in the stunner or inadequate carbon dioxide concentration.

Effectiveness of stun may be monitored by recording signs of recovery of animals, both immediately after stunning and

P.558

then on the bleed rail at a point 50 s from stun point in cattle and 35 s for pigs. These may include the return of eye and righting reflexes and rhythmic respiratory movements. Legislation and guidelines for duration and voltage required for stunning and for stun to stick times, as well as other aspects of handling, slaughter and killing, have been informed to a large extent by scientific research. This work has included analysis of spontaneous electrocorticograms (ECoGs) and visually evoked responses (VERs) or somatosensory evoked potentials (SEPs) taken during stunning and slaughtering performed under various conditions. ECoGs measure electrical activity in the brain; an electrical pattern similar to an epileptic fit is thought to signify insensibility of the animal, as people with epilepsy have no memory of events occurring while experiencing a fit. VERs are measured by implanting an electrode in the visual cortex of an animal and then shining a light source into the animal's eye. Where no electrical response to the stimulus is recorded, the animal is considered to be insensible. SEPs are measured by a similar method, but using a mechanical stimulus, such as a pin-prick.

If signs of recovery of animals on the kill line are seen, stunning tongue positioning may be observed and, if necessary, corrected; duration of stunning may also be recorded and corrected if inadequate. Additionally, stun to stick times may be recorded and sticking techniques monitored. Poor bleed-out due to small stick holes in pigs may delay brain death. Although large stick holes may increase risk of contamination in the scald tank, trimming of stick holes is a viable option, which avoids risk of poor bleed-out and recovery of sensibility prior to death. In cattle a thoracic cut, where all vessels leaving the heart are severed, is essential for rapid bleed-out.

Concentration of carbon dioxide and duration of exposure of pigs may be checked where signs of ineffective stunning are seen after controlled atmosphere stunning. A gondola or pig may be marked and timed from entry to exit of the stunner. As a guideline, pigs should be exposed to a concentration of carbon dioxide of at least 90% for 60-100 s in order to produce an effective stun under commercial conditions. There is experimental evidence that inert gases, such as argon, are less aversive to pigs than is carbon dioxide, and research into appropriate gas concentrations and mixtures and effective duration of immersion in these atmospheres is being carried out; effective exposure duration for a 95% argon atmosphere is thought to be >180 s. Gas stunners incorporate a gas concentration monitor. However, the concentration of gas in the stunner varies with position, and the monitor will indicate the gas concentration only at the location of the monitor. If it is placed near the bottom of the stunner, pigs may be exposed only to the display concentration for a part of the time that it is in the stunner - the remainder of the time they will be exposed to lower concentrations. An independent measure of carbon dioxide concentration, at several sites in the stunner, may be necessary. Where signs of recovery of pigs are seen on the line, line speeds may be reduced until no further recovery events are recorded during monitoring.

Poultry

Poultry are usually stunned in an electrically charged water bath, followed by automatic or manual neck cutting, but may also be killed outright in a controlled-atmosphere chamber. In parts of Europe 90% carbon dioxide stunning is used, which is currently only possible under a legal derogation in the UK, where either 90% argon or inert gas and 2% oxygen or 25-30% carbon dioxide and 60% argon or inert gas, in atmospheric air, is required for controlled-atmosphere stunning and killing. Research into the use of alternative gases and gas mixtures is being carried out. Some low-frequency electrical stunners may kill the bird outright, through cardiac arrest, but high-frequency equipment causes only a stun.

An effective stun causes birds to vibrate gently with wings held away from the body; rhythmic breathing and eye movements are absent. Birds may miss the water bath and so be non-stunned due either to head arching or incorrect water bath height. Additionally, where there has been uneven growth of birds in a flock, smaller birds may miss a stunner that has been adjusted to be correct for the average size of bird. However, even where all birds enter the water bath, some may not be stunned. This is because variable impedance of birds, or the leg shackle contact point, may result in birds receiving different currents, which, where a bath is set at the minimum 'effective' voltage in order to reduce carcass damage, may result in some birds receiving insufficient current to cause a stun.

Recovery of birds on shackle lines may also be due to failure to neck cut by either manual or automatic cutters. During manual cutting, commonly used to kill turkeys, birds may be missed due to operator fatigue and/or fast line speeds, while automatic cutters may miss birds due to incorrect height adjustment, uneven bird size or neck arching by non-stunned birds. Failure to cut birds may result in conscious birds entering the scald tank.

Where birds are being inadequately stunned, or stunned but not neck cut, the line speed may be reduced and additional back-up personnel placed at the stun bath, neck cutter and at the bleed line to re-stun or cut affected birds. Water bath and neck-cutter heights may be adjusted and water bath voltage increased. Birds may be re-stunned with a hand-held electric stunner or may be decapitated. A recently developed commercial percussion stun/killer, as illustrated in Fig. S.5, is more effective and humane than decapitation.

Welfare issues in minority species

The slaughter and killing of each minority species, such as **rabbits, ostriches, deer**, wild boar and **horses**, have specific welfare problems. Common to most of them, however, is the fact that slaughter facilities may be widely spread geographically, causing prolonged transport times and associated feed and water deprivation and fatigue. Species-specific handling and slaughter equipment that has been tested for efficacy may not be commercially available, with the result that equipment designed for more common species is modified without any appropriate testing. Additionally, there may be little scientific evidence available to determine correct handling, stunning and slaughter techniques, including correct voltages and stun durations. Restraint may be problematic where animals have only relatively recently been domesticated, such as ostriches, deer and wild boar.

There is some ethically based controversy about horse slaughter for meat in developed countries, as these are regarded as companion animals by many people; horse slaughter in these countries may therefore be carried out with maximum secrecy and welfare issues may remain hidden. Horses are usually killed in a similar way to cattle, using a captive bolt and neck cut, although a rifle may be used in some countries. The most significant welfare issues in horse slaughter relate to very long journey times, water and food deprivation, injury and discomfort due to cramped and poorly designed transport vehicles and fighting resulting from fear and the mixing of animals. Double-decked horse transporters are to be phased out in the USA.

A specific problem for ostrich slaughter is identification of rhythmic breathing, which may be difficult due to spinal reflexes that produce contraction of limb muscles and may be confused with respiratory movement. An effective stun has been found for most birds, with an electrical stunning current of >400 mA at 50 Hz applied to the head only for at least 3 s, provided that they are bled within 60 s from start of stun. Exact current and duration of stun required vary with design of head electrodes, which is a subject currently under scientific investigation. Mechanical stunning using a captive-bolt stunner is possible, but hoisting the bird may be difficult as there is no tonic, or passive, phase to the epileptic fit produced. A captive needle pistol, using air pressure, has also been used to stun ostriches.

Due to difficulty in handling and transporting deer, they are usually killed in the field, either by rifle at a distance or by captive bolt. For stunning by captive bolt, deer may be restrained in an electrically operated crush, which lifts the animal's feet off the ground in order to reduce struggling and injury. Rifle shooting is less reliable than captive bolt stunning, and animals may suffer injury and distress for a significant period before being killed. A modified, hand-held electrical stunner, applied for 0.5 s using 130 mA, with a stun to stick time of <10 s, has been shown to be effective in deer provided that there is adequate head restraint.

Wild boar may be stunned using hand-held electrodes or killed with a rifle, either in the field or in a pen, or by using a shotgun. A minimum stunning current of 140 mA, achieved by applying 100 V, has been shown effectively to stun rabbits.

With an increased consumer awareness of food production methods and greater public concern for animal welfare, there is a risk that pre-slaughter handling, stunning and slaughter practices that are currently widely in use may become unacceptable. It is essential that these practices be carefully monitored and deficiencies immediately and effectively rectified. Active research to develop more humane and more reliable methods of handling, stunning and killing animals is imperative.

Slaughterhouse

A slaughterhouse, or abattoir, is a premise where animals are killed and slaughtered to produce food. A large slaughterhouse may also be described as a processing plant, especially where there is further processing of the meat produced. Slaughter is specifically the causing of **death** through loss of blood.

(SH)

Sleep

Sleep is characterized by a temporary period of inactivity and a raised response threshold. It is exhibited in a distinct **diurnal rhythm** and with a characteristic posture, usually with neck recumbency. For example, in cattle this is usually in the sternally recumbent position with the head either resting on the ground or tucked round and held against the thorax.

Four levels of alertness can be distinguished:

- Alert wakefulness (AW): eyes fully open, characterized by a low-voltage, fast-activity **electroencephalogram** (EEG) output by the **brain**.
- Drowsiness (DR): upper eyelids relaxed, increased **arousal** threshold and reduced alertness. Some high-voltage, slow-activity electroencephalogram (EEG) output.
- Quiet sleep (QS): eyes almost closed, increased arousal threshold and all EEG output of the high-voltage, slow-activity type.
- Active sleep (AS): eyes fully closed, all EEG output of the low-voltage, fast-activity type, some rapid eye movement (REM), heightened arousal threshold. Otherwise known as paradoxical sleep.

In diurnal species AW tends to predominate during the day and DR at night; for example, in cattle 52, 31, 13 and 3% of the 24-h day are spent in AW, DR, QS and AS, respectively. AS occurs only at night and often after a bout of rumination. Rumination often accompanies DR at night and may also accompany AW and occasionally QS. The state of QS in many animals is preceded by regular, monotonous actions like ruminating. Reticulo-ruminal motility is decreased at night, probably because of reduced basal metabolic rate during DR and QS. The normal transition is from AW to DR to QS to AS. Bouts of AS are short in cattle and horses in comparison

P.560

with other mammals, typically only 5 (cattle) to 15 (horses) min, but they are numerous. Hence, sleep in these species can be considered as polyphasic in contrast to humans, in whom it is monophasic.

Sleep is also characterized by its consistency, as patterns vary little from day to day when health is good but are specific to individuals. Occasionally during AS, animals demonstrate tachycardia, rapid breathing and/or limb movements, which are thought to be indicative of dreaming. The amounts of both AS and QS often decline with age.

There are two probable functions of sleep: immobilization and recuperation. In some animals regular, temporary immobilization is beneficial in guarding against **predation**, providing that the sleeping site is secure. In large, **grazing** prey animals this is often not the case, and hence most grazing ungulates have short sleep periods. In contrast, for most forest-dwelling prey such as the dormouse, safe sleeping sites are available and sleeping times are long, even extending to

hibernation in many species. Thus immobilization offers two evolutionary advantages - energy conservation, which is of use to predator and prey alike, and security from predation, since most predators search for moving prey.

Recuperation is likely to be of importance, since prolonged deprivation leads to a state of exhaustion, the exhibition of **abnormal** behaviours and even hysterias. However, there is no evidence that longer sleep patterns per se occur more frequently in more complex animals, suggesting that recuperation of brain function in general is not directly related to sleep duration. Indeed AS may specifically function to maintain the brain in a state of readiness during the subconscious state. Also, animals that are physically more active do not use sleep more as a method of recuperation. On the contrary, many inactive or sporadically active animals such as sloths, bears and lions sleep for long portions of the day. The choice of whether to become an active feeder for most of the day and minimize sleep, or whether to save energy by maximizing sleep, is determined by the security of the sleeping site and the rate at which the ingested food can be digested.

Sleep is therefore an important component in an animal's behaviour repertoire. Its inclusion in welfare indices is advocated by some scientists, although the duration of sleep per se is not directly related to **welfare** - disturbances in sleep pattern may be a more useful measure. Some modern housing systems, with high density of animals and low levels of comfort, may preclude adequate sleep in some animals, reducing their welfare significantly.

Social behaviour

Social behaviour refers to the behavioural interactions occurring between individuals of the same species or between different species that share some sort of structured relationship, which might be cooperative (**see: Cooperation; Social group**) or competitive. Social behaviours which promote social inclusion or cohesion within the group, e.g. reciprocal **altruism**, may be referred to as prosocial behaviours.

For a social interaction to exist one individual must first elicit a response from another (this may be termed a reaction), which feeds back to the first individual, i.e. there is a bidirectional exchange of information between the animals involved (**see: Communication**). Some species capable of interspecific social behaviour (**see: Interspecific behaviour**) may adapt their intraspecific behavioural repertoire in order to improve communication with another species. For example, meowing by the cat is rarely used intraspecifically but is commonly used during vocal exchanges with humans. However, interspecific social behaviour does not require that they view heterospecifics as **conspecifics**, as is sometimes implied. For example, dogs adapt similar social **play** sequences according to whether the play partner is another dog or a human and use different perceptual processes when interacting with the two species. None the less, many trainers and animal carers now recognize the potential value of using 'ethologically relevant' signals to improve social interaction with another species.

The potential for cooperative social behaviour often arises from the need or desire to achieve common goals efficiently, e.g. **reproduction**, distribution of **resources**, etc., and in this case a social **bonding** may exist between the two animals. This may be identified by a tendency to associate with the individual and **distress** when separated. Thus the patterning of social behaviours can be used to define the relationship between and role of individuals within the **social group** (e.g. least preferred and most preferred associates). In addition to behaviours associated with cohesion between individuals (including acts of affiliation, such as **courtship behaviour**, as well as **maternal behaviour** and **paternal behaviour**), social behaviour also includes interactions associated with the defence of resources against others (e.g. **aggressive behaviour**, **agonistic behaviour** and acts of **territoriality**), which, if persistent or of high intensity, can lead to **social stress**.

Although social **releasers** may result in the exhibition of fixed action patterns or **modal action patterns** from another individual, much social behaviour is typically quite variable, since social stimuli are less predictable than physical environmental stimuli to which behaviour may be directed. The response of one individual is dependent not only on the stimulus presented by the other individual, but also by its internal **motivational state**. Thus at one time a threat may result in withdrawal by an individual but at another time the same act may result in a reciprocal threat, for example if the individual is more hungry. Therefore, it can be useful to conceptualize social behaviour as collective expressions of individual, goal-directed strategies (which may be compatible or not) by more than one individual in a group, which affect other individuals.

However, this is not to say that genetic factors are not important in the expression of social behaviour, and sociality is a heritable trait (**see: Personality**). The relative importance of genetic factors to the evolution of social behaviour is debated and a focus of **sociobiology**. Clearly, genetic factors are important to the evolution of sociality, which, with its associated advantages and disadvantages, affects the evolution

P.561

of social behaviour in any given context. Disadvantages include: (i) the potential costs associated with increased competition for breeding- and feeding-related resources; (ii) increased **disease** and **parasite** burden risk; (iii) increased exposure to **predation** as a result of a group being more conspicuous; and (iv) increased risk of exploitation by others, any or all of which can result in particular types of social behaviour and related social **cognition**. For example, it has been suggested that the risk of exploitation by others within a social group (itself a potential form of social behaviour) may have been a key driver in the evolution of a range of complex problem-solving abilities.

Advantages to sociality include: (i) increased defence capacity against predators and protection of young; (ii) greater potential to identify and exploit important resources in the environment (such as food and mates, although competition following identification may be increased) and the ability to exploit different ecological niches; (iii) improved population stability; and (iv) the ability to modify the environment (rather than be modified by it) - all of which depend on the development of related social behaviours. Psychological benefits and associated health benefits may also arise from certain social behaviours - for example, mutual **grooming** in some species has been shown to result in lowered **heart rate**, as well as **oxytocin** and **endorphin** release, which may be associated with relaxation and affiliation. The relative importance of these potentially beneficial and detrimental factors to any given species can be expected to affect the nature of social behaviours expressed in relation to the given context.

Historically, the study of the social behaviour of animals in **captivity** has given great emphasis to competitive interactions between individuals over resources and the significance of hierarchy as a consequence of which there may be reduced physical harm and social stress. This emphasis may in part be an artefact of spatial restrictions and the limited distribution of high-value resources within many **captive animal** systems, which may lead to increased competitive behaviour (see Lockwood, 1979). Another challenge relates to the interpretation of competitive social interactions, with some authors emphasizing the importance of the assertion of **dominance** and eliciting **submissiveness** in other individuals as a result. Submissiveness is thus defined as the response associated with yielding to a display of threat by another, and so is a response that follows threat. However, such a sequence of events might imply social instability or uncertainty, since aggression is a divisive and potentially risky behaviour used when in response to a threat to resources. By contrast, yielding or avoidance before any threat is more conducive to maintaining social relationships. It is perhaps useful to distinguish this from submissiveness as defined above, and refer to it as deferential behaviour, since it pre-empts unnecessary stress and reflects a more healthy social situation.

A third related term, **appeasement**, might also be usefully distinguished. This refers to behaviours expressed after a social conflict aimed at restoring good social relations. After a dispute, there is a risk that the loser may be rejected from the social group, which would greatly reduce the individual's biological **fitness**. Appeasement gestures (also referred to as post-conflict resolution behaviours) may serve to reduce this risk. Whereas the primary function of deference and submissiveness is to communicate a willingness to yield in different circumstances (avoidance versus termination of threat), the function of appeasement is primarily to maintain social cohesion.

Unfortunately, some species appear to use at least some of the same behaviours (e.g. head turning away in the dog) in different circumstances and, if the context is not clearly defined, this can lead to confusion about the relative importance of different social behaviours. While increased competition with **conspecifics** is undoubtedly an important cost to social living, it is worth remembering that social living and its associated behaviour arises from an intrinsic attraction between individuals. Thus communication, coordination and cohesion should perhaps be considered the fundamental basis of social behaviour more than competition. In cases of social tension involving **companion animals**, it is increasingly recognized that

it is preferable to encourage deference rather than to try to assert dominance, since the former strategy is logically less stressful, more socially harmonious and therefore more conducive to good welfare.

Early exposure at particular times (**see: Sensitive phase**) and social play appear to be very important in shaping the social behavioural repertoire and skills of an individual, as well as defining the range and type of individuals to which social attraction may be exhibited (**see: Socialization**). Inappropriate or limited opportunity can give rise to a range of behaviour problems, such as **aggression** to unfamiliar types, which also reflect a welfare problem associated with social anxiety. Other problems can arise as a result of unmet social behavioural goals, and include problems such as excessive **vocalization** and **separation anxiety** by dogs when isolated from their social attachment figures.

Social cognition

Social cognition is the sum of the processes that deal with information coming from, or relevant to, other animals. It integrates a variety of social phenomena, such as **communication**, social recognition, **social learning**, **cooperation**, social bonding, inference of relationships between other individuals and, sometimes, **theory of mind**. Research on social cognition first focused on primates, but has since extended to many other species. There is now a growing body of data on fish (e.g. guppies) and invertebrates (e.g. octopus) that benefits the field of comparative social cognition and thus the understanding of the mechanisms, function and evolution of social cognition.

Depending on their sociality level and thus on the complexity of their social environment, different species may

P.562

have evolved different socio-cognitive abilities. It is the basis of the social complexity hypothesis that suggests that living in stable, socially complex groups favours the **evolution** of social intelligence. This idea has been applied and validated, for instance, in primates but also recently in birds (corvids), by comparing the performance of highly social and relatively asocial species in socio-cognitive tasks.

Research on social cognition has also been stimulated, especially since the late 1980s, by the **welfare** implications of socio-cognitive abilities in domestic species. Information gained from social partners through their behaviour, or from other channels of communication, is indeed a major factor affecting how animals adapt to their social and non-social environment, especially when this environment is complex and artificially manipulated by humans. Domestic animals do not cope (**see: Coping**) equally with the various challenges of their rearing environment (e.g. crowding, social instability, foraging, potentially stressful human interventions, instrumental learning) due to differences in their socio-cognitive abilities (**see also: Social stress**). Knowing more about the cognitive capacities of animals and about how they use social information according to the quality of social bonds between individuals and their social motivation can thus facilitate interventions aimed at lowering **fear** responses or favouring the acquisition of appropriate instrumental responses through better-adapted management practice (e.g. use of knowledgeable conspecific demonstrators), hence enhancing the animals' welfare.

Social facilitation

Social facilitation occurs when the presence of a **conspecific** changes the motivation of the observer and its behaviour, resulting in the tendency of individual animals to do what other individuals are doing. This phenomenon can be considered as social influence but not as **social learning**, as it leads only to an increase in performance of a behaviour already known and stops when no other individual is present. Social facilitation takes part in synchronization of various behaviours, such as **feeding** behaviours, for instance.

Social flux

Social flux describes inconsistent **group** membership in social animals. Groups with a high social flux have higher intra-group **aggression** rates compared with groups of low social flux. They can form temporary intra-group social bonds (often with kin) and have stable numbers, but nevertheless depend on immigration to maintain their numbers. Changes in group membership can be due to high **mortality** or dispersal rates or movements among groups because of overlapping **home ranges**. They can also be due to human manipulation of certain sex/age classes, resulting in a skewed sex ratio and thus relatively high inter-group transfer of one particular sex. For example, many **feral** horse populations have skewed sex ratios due to removal of males by humans, and this leads to increased social flux (Linklater, 2000).

Social flux in feral dogs has been shown to result from widespread **resource** distribution and, particularly, from variation in the predictability, dispersion and richness of food sources, as well as cooperative hunting techniques and fluctuating density of predators (MacDonald and Carr, 1995).

In the domesticated situation, high social flux can lead to considerable welfare concerns in socially kept animals. Higher aggression rates can lead to increased instability or injuries, and thus to **stress**. To prevent stress, the animals must first be raised and kept in **social groups**, preferably with peers as well as older animals present, provided that this is part of the species' natural social organization (**social behaviour** is partly a learned process). Secondly, sufficient knowledge of species-specific natural behavioural requirements can lead to **welfare**-friendly enclosure designs and appropriate **grouping**.

Social group

Social groups are more than simple collections of individuals: the animals make an effort to stay together. A social group may be defined in terms of its composition (characteristics of individuals making up the **group**), social structure (type and quality of relationships and interactions occurring between members of the group) and dynamics (rate of change in membership of the group). Groups are often recognized by a consistent set of social relationships and interactions between members of the group. Their members share similar goals and interests and may include genetic relations.

Within a group of social animals there tends to be a leader or leaders and followers, and the leading animal can change depending on time and circumstance. This is sometimes associated with the presence of a **dominance hierarchy**. However, dominance hierarchies can also be observed within non-social groups if forced into close contact. Social groups of animals are also identified by their affiliative preferences, coordination of activity, **communication** between individuals within the group and division of labour. For example, some groups, called eusocial (**see: Eusociality**), are highly organized and are characterized by reproductive division of labour. Some members have lost their reproductive capability and become workers, while others retain **reproduction** and are breeders. All members of the eusocial group work to increase the reproductive output of the colony (**see: Inclusive fitness**). This type of social group is often found in ants, bees, wasps and termites, but can occasionally be shown by vertebrates, like the naked mole rat.

In contrast to social insects, social groupings of vertebrates are not fixed or species specific. They depend on numerous

P.563

factors, such as the available food supply, population density, ages of individuals and male: female ratios. There are benefits and costs to living in a social group that affect the size, structure and dynamics found. Some social groups are made up of monogamous pairs of animals, while others only form social groups at certain times of year. For example, blue tits vigorously defend nesting sites from other birds during the breeding season, but flock together in groups during the winter months for increased predator protection and food location.

Social interaction test

The social interaction test was developed in rats by File and Hyde in the late 1970s to measure anxiogenic and anxiolytic drug effects. It relies on a natural spontaneous behavioural response (i.e. unconditioned response) like other animal models of **anxiety**, such as the **elevated plus-maze** or the **light/dark test**. The social interaction test is based on the observation of active **social behaviours** in a pair of unfamiliar animals. The time they spend performing social investigation (i.e. sniffing a partner), social contact (e.g. **allogrooming**) or play-fighting is the dependent variable measured. A decrease in social interaction is then indicative of an anxiogenic effect, whereas an anxiolytic effect is revealed by an increase in social interaction and motor activity. As the novelty of the environment and light are mild **stressors** for rodents, different levels of anxiety can be generated by manipulating those factors that will result in the test being more sensitive to anxiolytic or anxiogenic effect detection.

From a **welfare** point of view, the social interaction test has the advantage over some other models in its avoidance of the use of water or food deprivation and electric shock. From a practical point of view, it is a quick test to perform as it does not require extensive training of the animals. Recently, a modified version of the social interaction test that also allows measurement of social **motivation**, by providing the test subject with an opportunity to escape from its partner, has been developed.

While this test was first validated in adult male rats, recent studies showed that it seems to provide sensitive and consistent results across age groups, and can also be used successfully in female rats and other rodents such as mice and gerbils. The social interaction test has played a major role in giving further insight into the neural basis of anxiety, and is also used to help determine the genetic basis of anxiety disorders. Recent work also suggests that this model could be used for studying the neurobiology of social behaviour. The social interaction test paradigm is not only sensitive to a number of physiological factors that can affect anxiety, but can also be used to assess the effect of environmental factors (e.g. **handling, housing**).

Social learning

Social learning occurs when an individual learns by observation of another individual (i.e. demonstrator). Such learning has been demonstrated in various species, from fish to birds and mammals, and seems to be potentially influenced by sex, age, social rank and the social relationship between the observer and demonstrator. Social learning can take place between **conspecifics** or heterospecifics, including humans as shown in dogs, dolphins and primates. The mere presence of a demonstrator and the subsequent modification of the observer's behaviour do not necessarily imply that social learning has occurred. Social influence such as **social facilitation** (i.e. increase of performance of a behaviour already known in the presence of other individuals) could indeed then be at **play**. Social learning can be assumed to take place when the observer performs better only after he/she has seen the demonstrator performing the behaviour and if he/she still subsequently displays this behaviour when the demonstrator is absent. It can imply a variety of behavioural processes:

- **Local enhancement** (observer attracted toward one particular object) and stimulus enhancement (observer attracted toward any similar object): the acquisition of the behaviour to be learned is facilitated by increasing the frequency of the observer's behaviours directed toward the location or object in question following the demonstrator's presence near or interaction with the object.
- **Social goal emulation**: the observer is thought to realize what the demonstrator's goal is and then displays its own pattern of action to achieve the same goal.
- **Imitation**: defined by Thorpe as the copying of a novel or otherwise improbable act for which there is obviously no instinctive tendency; the existence of imitation in animals has been the subject of a lot of debate, especially because some researchers claim that imitation is a prerequisite for the existence of animal **culture**, but recent results argue for imitative behaviour in some species.

Social learning has been showed to play a role in the acquisition of various behaviours such as, for instance, food **preferences**, **foraging behaviour**, **mate choice** or **predator avoidance**. It has an adaptive value when individual learning by trial and error would be too costly (e.g. learning to avoid eating toxic plants), and can be taken advantage of in the context of animal welfare to facilitate the adaptation of domestic species to their rearing environment.

Social parasite

Social parasites are individuals that increase their **fitness** by non-fatally exploiting the **social behaviour** of others. A true social parasite should exhibit some dependence or adaptation associated with the behaviour, which can be inherited, in order

to distinguish from incidental exploitation of available resources. It is often thought of in terms of interspecific interactions; for example, cuckoos exploit the parental behaviour of other species (brood **parasitism**), and many insects exploit chemical **signals** to obtain food from eusocial species (**see: Eusociality**); however, it may also be intraspecific, with some considering certain forms of exploitation of one sex by another as a form of social parasitism (**see: Sexual selection**). Social parasitism is also sometimes known as involuntary **altruism**.

(DSM)

Social releasers

Social releasers are significant biological stimuli that play an important role in the display of **ritualized behaviour** of many animals. These releasers can be chemical, visual or auditory, and elicit various types of behaviour such as, for instance, **sexual behaviour**, anti-predator behaviour or **maternal behaviour**. Social releasers are generally considered as being more complex in their nature and in the response they provoke than **sign** stimuli, which are based on simple structural characters or movements that set off a single, stereotyped response pattern.

Social stress

If stress is an organism's attempt to maintain **homeostasis** in response to environmental challenge, then social stress refers specifically to challenge originating from the social environment, in particular that associated with the presence and absence of **conspecifics** or their cues, since the potential contribution of non-conspecifics to the social environment is as yet unclear. It therefore has the potential to influence, at least to some extent, the lives of all those higher animal species that engage in social contact. Social stress can result from direct interactions with conspecifics, either familiar or unfamiliar, or in response to indirect encounters with conspecifics - for example, exposure to olfactory or auditory cues. In addition, social stress can be used to refer to situations where (preferred) social contact is absent, such as is the case during social **isolation** or separation from a peer **group**.

Examples of situations when social stress may occur for some species include: (i) exposure to unfamiliar conspecifics; (ii) dominant/subordinate relationships; (iii) maternal/infant separation; (iv) peer group separation; (v) isolation; (vi) mixing or introducing new individuals; (vii) crowding; and (viii) **sexual behaviour**. These situations may be especially relevant for animals that are held in captivity, because normal behavioural responses to social stress, such as escape, may be impossible.

'Acute' social stress describes a response to either a mild or severe social challenge that is short-lived, and can be considered to be **adaptive**. It may therefore be expected to have little long-term effect, if any, on an animal's **welfare** unless it is particularly severe (e.g. an acute stress with a chronic (long-term) consequence). 'Chronic' social stress, on the other hand, describes a response to either a mild or severe long-term social challenge. It may result in significant behavioural and neuroendocrine changes and, ultimately, in pathological consequences (see later) reflecting an animal's inability to cope with/adapt to the challenge. It can therefore have a major impact on animal welfare. In addition to the physical effect of social stress, there is also likely to be an emotional component to social stress with, for example, animals attaining negative states of **fear** and/or **anxiety** when reacquainted with individuals that have previously defeated them in an aggressive encounter. This combined effect of the emotional and physical response to the challenge of social stress makes it a key component of animal welfare research.

Although the use of the term 'social stress' is intended to separate it from other potential sources of stress, in reality there is often great difficulty in differentiating between the specific causes of stress, be they either social or originating from some other aspect of the environment - and different sources of stress may result in qualitatively different physiological, immunological and behavioural responses. If we were to study the effect of increased housing density on broiler **chicken** welfare, for example, can we differentiate between potential **stressors** from the physical environment (e.g. enclosure size, room temperature, ammonia levels, etc.) and those from the social environment (e.g. crowding) - especially if the different stressors induce different, potentially contradictory, responses? Even within the potential social stressor of crowding we find that there are many different potential components of social stress, such as proximity of individuals, group size,

activity and competition for resources. It can therefore be concluded that the response to social stress is generally non-specific, in that the outcome may be influenced by many different variables.

The resulting response of animals to social stress is also subject to great variability. It can depend, for instance, on the species, strain, sex, age, status and previous social experience of the particular individual involved. For example, if two **pigs** are about to fight each other, both may respond to the stress of the encounter, but they may both respond differently according to the outcome of previous aggressive interactions that they have experienced. Thus, the threat of further aggression could be less stressful for a previously successful pig than for one that has been repeatedly defeated. In addition, individuals with different **coping** strategies (active/proactive and passive/reactive) may react differently to stressful situations, and/or the way that each individual animal perceives and evaluates a given social situation may result in further variation. In other words, we might expect different patterns of response to social stress in different groups of animals, with behavioural, physiological and immunological responses to stress varying between groups, and also between individuals within those groups.

While the social environment is a potential source of stress, it is also the reason why individuals group together - even if it may occasionally appear against their own immediate interest. Emphasis on the negative aspects of the social environment often blocks appreciation of the positive aspects of living in a social group, such as anti-predator effects, foraging benefits, reproductive benefits, thermal regulation, positive affiliative relationships and social support. Living in a group can actually help to reduce the impact of environmental stressors by influencing an animal's psychological state; for example, the presence of unafraid companions decreases the stress response to the threatening presence of a human. There are therefore

P.565

many advantages to living in groups and, particularly in free-living animals, these may outweigh the potential costs of social stress. Besides, in a stable social group, much of the social stress observed during the formation of a social **hierarchy** (e.g. dominant/subordinate interactions) is quickly over and remains at low levels (i.e. acute social stress) - so this apparently 'negative' stress is adaptive, and may not necessarily indicate poor welfare in the longer term. Once the social hierarchy has been established, any other potential causes of social stress (e.g. the arrival of interlopers or separation) are rare. Problems arise when there is either a threat to the stability of the group or the group composition is unbalanced, and this is frequently the case for captive animals due to the constraints of **captivity**.

Under captivity, formerly acute and tolerable levels of social stress may become chronic due to human influences, such as mixing (e.g. sows coming out of **farrowing crates**), crowding (e.g. high stocking densities for broiler chickens), spatial restrictions (e.g. laying hens in battery cages) and the formation of an unbalanced or unrepresentative group structure (e.g. **zoo animals**). This can result in increased behavioural, neuroendocrine and possibly emotional changes that may compromise welfare. Despite this apparent reduction in welfare, singly housed individuals (e.g. laboratory **rats**) will still work for access to social contact - thus it appears that the 'benefits' of living alone, i.e. avoiding the potential stress of direct social interactions, are outweighed by the costs, i.e. no direct interaction at all, of isolation. Although this is likely to be a species-specific and context-specific response as, for example, chickens in a safe and familiar environment will often show preferences for being alone.

Perhaps we should therefore accept that, as a result of their genetic heritage, the priority of most social animals will be to seek social interaction, despite the consequences. However, this priority for social interaction has now been compromised by human influence to such an extent that the benefits of group living may become redundant, and the costs of group living may be far higher than for free-living groups, resulting in the development of chronic social stress and hence poor welfare. For example, the constraints of captivity may induce a lack of both controllability and predictability to the social interaction. Interactions may be inescapable due to confinement (e.g. within cages/pens), with escape attempts by subordinates frustrated. Indeed, it may be as stressful, or even more so, being dominant as it is being subordinate. In captivity, dominant individuals (e.g. laboratory mice) may become as stressed defending their social position in the continued presence of rival animals as their subordinate rivals become from being unable to escape the presence of their social superiors.

Selective **inbreeding** of domestic species/strains may have resulted in the production of increasingly homogeneous individuals. For example, inbred strains of mice are derived from 20 or more consecutive generations of brother/sister (full sibling) matings. This may not only cause **communication** problems between animals, resulting in unnecessary or inappropriate aggression rather than non-fighting assessment, but also problems with the formation of a stable social hierarchy. If, for instance, all the animals in one group have very similar social strategies, e.g. all aim to be dominant, then this serves only to increase conflict within the group. This issue of group composition may be as important for determining the level of social stress in a group as other, more obvious, social stressors such as personal space allowance. Another

effect of captivity is that, even in groups that are potentially able to form stable social hierarchies, such an attempt may be continuously disrupted by the introduction or removal of individuals from the group. An example of this is seen on pig farms, where individual sows are removed for, and subsequently reintroduced after, farrowing.

In an attempt to try and reduce the influence of multiple variables, several models of social stress have been devised, and these are studied predominately under laboratory conditions and using **rodents**. The most commonly used models include the social defeat model, the social instability model and the social disruption model. These three models focus on agonism as a source of social stress. The social defeat model involves one or more direct aggressive encounters between the naive subject and an 'attacker'. By concentrating on two individuals with known social backgrounds, this model can be fairly reliable about interpretations of the data in terms of an interaction + defeat (or interaction + victory). Social instability models involve the formation of stable groups of individuals that are then mixed together whereas, for social disruption models, high-aggression individuals are introduced into previously stable groups. In contrast to the social defeat model, neither the social instability model nor the social disruption model can be so reliable about the specific source of any social stress expressed by the subjects - because the subjects may have experienced victories or defeats due to the group housing.

But how can we identify when an individual or group is experiencing social stress, and how can we then identify when that level of social stress is threatening welfare? Some 'indicators' of social stress may be more likely than others to demonstrate that an animal is suffering a decrease in welfare due to social stress. Such indicators will only result either from prolonged exposure to social stress, e.g. pathology and abnormal behaviour, from exposure to extreme stress (e.g. gastric ulceration) or that attempt to reveal the subjective state of an animal (i.e. what it feels), e.g. anxiety tests.

The majority of indicators, e.g. aggressive behaviour, indicate the presence of social stress in general - without allowing us to determine whether welfare is threatened. In addition, the absence of any of these indicators does not necessarily indicate an absence of social stress. Our predictions for what behavioural and endocrine responses to social stress we might expect will also depend strongly on the time at which the measure is taken after the social 'challenge', e.g. immediately after mixing or 24 h later, and the precise time of day/night/year that the indicator is measured if the indicator is affected by **diurnal/seasonal rhythms** or motivational influences.

Common behavioural 'indicators' of social stress include (among others): (i) agonistic (i.e. aggression + defence) behaviour; (ii) general activity; (iii) social investigation; (iv) self-directed behaviour (e.g. tail manipulation in rats); and (v) abnormal behaviour, including **stereotypies**. Abnormal behaviour may develop when the natural adaptive response to a social stressor is frustrated due to the constraints of captivity,

P.566

and an animal no longer has control over its environment. For example, bar-biting in laboratory rodents may represent frustrated attempts by individuals to escape from social conflict. Such behaviours may therefore suggest the presence of welfare-threatening chronic social stress.

Further behavioural changes that can be associated with social stress include: (i) emotionality-linked behaviours such as anxiety and performance in anxiety tests, e.g. the **elevated plus-maze**; (ii) alcohol/sucrose consumption; (iii) sexual behaviour; and (iv) **preference** and consumer demand tests (although it should be noted that the effect of social stress itself may act to disrupt an animal's ability to make an accurate decision, because of its effects on learning and **memory**).

Several different measures of immunocompetence can be measured, all based on the premise that stressed animals have increased activation of the **hypothalamic-pituitary-adrenal (HPA)** axis and therefore increased levels of corticosterone/cortisol that can be immunosuppressive, i.e. can suppress immunity. Few measures are specifically related to the measurement of social stress, but are used to assess a general, non-specific stress response. These include (among others): (i) peripheral lymphocyte counts; (ii) lymphocyte proliferation; (iii) salivary/faecal immunoglobulin A (IgA); and (iv) serum total immunoglobulin G (IgG).

Physiological 'indicators' include (among others): (i) weight loss (or reduced growth); (ii) an increase in HPA activity (especially an increase in the level of cortisol/corticosterone in blood plasma and/or saliva; (iii) **glucocorticoid** metabolites in urine and/or faeces); (iv) an increase in **sympathetic nervous system (SNS)** activity (e.g. increase in the levels of adrenaline in blood plasma and tyrosine hydroxylase in the **adrenal glands**); and (v) an increase in **heart rate**, reproductive success, **blood pressure** and body temperature. Examples of pathologies that can occur as a consequence of chronic social stress include: (i) an increase in adrenal weight (adrenal hypertrophy/hyperplasia); (ii) a decrease in thymus weight (thymus involution); and (iii) an increase in gastric ulceration.

Social stress can also generate changes in neurochemical transmission in the **brain** with, for example, increased serotonergic activity in response to social stress that may relate to the role that **serotonin (5HT)** plays in mediating social

behaviours, including aggressive and sexual behaviour. Social stress can also influence **corticotropin-releasing hormone** (CRH) and mRNA levels in the paraventricular nucleus region of the **hypothalamus** - where most CRH is synthesized. CRH is critically involved in the instigation and control of HPA axis activity.

In all cases, whatever the 'indicator', the prediction that we make about how a group/individual might respond to the challenge of social stress is specific to each particular instance, and therefore cannot be generalized. Care should also be taken when interpreting the results of potential 'indicators' of social stress. Commonly used physiological and behavioural indicators of social stress - for example, heart rate and general behavioural activity - may increase during an **aversive** agonistic encounter with an unfamiliar conspecific, but a similar increase may also be observed during, presumably positive, sexual behaviour. In addition, an increase in heart rate might also be expected with any increase in general activity levels - even in the absence of any stressor, social or otherwise - i.e. we should be sure of the functional significance of the indicator.

There are several different approaches to the welfare problems that can be posed by social stress. One approach is to decrease aggression (e.g. during the mixing of **weaner** pigs) by either the use of drugs (e.g. tranquillizers) or altering the environment in some way (e.g. mixing groups in the dark). However, these may only serve to hide/delay the problem rather than address the initial cause of the issue itself. Olfactory cues such as boar taint may reduce aggression during the mixing of weaner pigs, because the smell of the dominant individual may suppress aggression in groups of subordinate animals; however, this may also cause a state of fear or anxiety in the other animals if they associate the smell of the dominant individual with previous experience of defeat.

Another approach is to attempt less interference by humans, i.e. reduce the constraints imposed by captivity. This can be done by identifying those situations/procedures most likely to result in social stress and either reducing their frequency or avoiding them entirely, in order to both encourage stability and promote the beneficial effects of affiliative relationships and social support, e.g. reduce the amount of mixing and separation of groups.

However, we should not attempt to avoid stress entirely, as this would create problems of its own. Indeed, in some instances (e.g. zoos) the introduction of controlled levels of stress may be used to improve welfare. Good husbandry practice should ensure correct provision of resources in order to reduce competition. If a food trough is placed at the end of an enclosed corridor and there is not enough room for all the animals in the group to feed at the same time, then this will increase the chances of aggressive competition or **resource** monopolization by particular individuals, to the exclusion of the others. Attention can also be directed towards trying to create the 'best' possible group composition, e.g. by mixing active and passive coping strategists, higher- or loweraggression animals or individuals with a range of sizes. In this way we might facilitate the use of non-fighting assessment as a means for individuals to discriminate between one another. Finally, the creation of suitable space(s)/barriers within the social environment may allow room for escape or shelter - however, as for all environmental modifications, you have to be sure that these are actually beneficial, as in some species alterations to the environment may lead to an increase in aggression rather than a decrease.

Socialization

Socialization is the process by which animals adopt the behaviour patterns appropriate to the social environment in which they live, allowing them to coexist/interact with other individuals. It is through this process that social preferences are formed and the species identity of a young animal is established. An animal is said to be 'socialized' when interacting with another animal if it displays a recognition and acceptance of it, and behaves accordingly towards it.

The adaptability of behavioural tendencies is most rapid during the early stages of their lives and declines with age. Four consecutive, interrelated phases of behavioural development have been suggested. These are: the **neonatal period**, the **transitional phase**, the **socialization phase** and the **juvenile period**. The duration of these stages varies between species. Experiences during the early stages of life appear to be more important than those occurring during later life, with the socialization period playing a major role in determining social behaviour in adulthood, and a disruption of this process resulting in profound influences on adult behaviour.

The process of socialization does not necessarily cease at the end of the socialization phase. While social behaviour is most amenable to modification at this time, if the animal has not been socialized during this period the formation of social relationships can still occur. Remedial socialization has been attempted in a number of species, such as the **cat**, **dog** and **pig**, with some success. Socialization also appears to be reversible to some extent and requires reinforcement into adulthood. For example, puppies that are initially well socialized to people have been found to become less friendly if they are subsequently housed in kennels and receive minimal human contact. This may be a consequence of stress-induced **dishabituation**.

The basis for socialization and the formation of social bonds in mammals has generally been attributed to the concept of **attachment**, with the formation of inter- and, in some cases, intraspecific relationships during socialization being influenced by the social organization of the species. The formation of social bonds has been studied in many species, with arguably some of the most dramatic attachments demonstrated by the **imprinting** process in **precocial** birds such as geese and **chickens**. Precocial animals, whose locomotor and sensory abilities are well developed at birth, have a shorter sensitive phase during which socialization occurs, with imprinting playing an important role in the formation of social behaviour (Belyaev *et al.*, 1985). Filial imprinting is the process whereby the newly hatched young become rapidly attached to parents or surrogates, independently of the consequences of the behaviour.

Konrad Lorenz's studies of filial imprinting in waterfowl led to the idea of a fixed period in a rigid sequence of development, during which environmental influences have a profound and irreversible effect on subsequent social behaviour. Although the term 'imprinting' is usually associated with precocial birds, the concept of a period of sensitivity can also be applied to the development of social behaviour in **altricial** species. In mammals, the concept of a '**critical period**' in behavioural development is more usefully replaced with that of a '**sensitive phase**', during which the formation of social attachments is facilitated. The end of this phase coincides with the appearance of fear in many species, possibly related to the maturation of the pituitary-adrenal system. In most animals the first interactions occur with the mother, particularly in altricial species, which tend to form strong mother-infant attachments. Secondary socialization appears to involve social play, with littermates or peers.

Species identity is not strictly genetically pre-programmed. Social behaviour may therefore be directed more broadly towards humans and other species in a domestic situation. The ease with which **wild animals** become domesticated is also undoubtedly influenced by their species-typical patterns of social development. While species-specific sexual behaviour is essential (this appears to be a separate process, possibly dependent upon other innate stimuli), social attachment has a learned component.

Humans have been able to exploit this process, thereby enabling the animal to at least tolerate, and often value, the presence of people. Indeed, the process of intentional socialization is central to producing animals to fulfil the role of human companions and in the training of animals for certain working roles - for example, livestock-guarding dogs. The sensitive phase for socialization seems to be longer, with less sharply defined boundaries in domestic animals compared with wild animals (hence the use of the term phase rather than period), and this phenomenon has been demonstrated experimentally through the selection of silver foxes for domesticated traits (Belyaev *et al.*, 1985). While the ability to

socialize with people may, in part, have resulted as a consequence of **domestication**, this phenomenon is also present, to some extent, in many wild species, with handreared individuals often displaying affiliative behaviours towards people.

In order to understand adult behaviour, it is necessary to understand the **ontogeny** of that behaviour. However, because of the speed with which it occurs, it has proved difficult to study the development of social behaviour and it is not clear what types of interaction are required for normal social development. Several different experimental approaches have been used to examine the process of socialization. These include deprivation experiments, in which the animals are subject to varying levels of opportunity to socialize to other individuals (Harlow and Harlow, 1962). In many of these experiments extreme social isolation is accompanied by spatial or sensory deprivation, and individuals are also subjected to the stress of being taken out of a restricted environment for testing, giving rise to the criticism that the **abnormal** behaviours observed may be the result of any of these factors.

Cross-fostering experiments, in which an individual of one species is removed from its **conspecifics** at birth and reared with individuals of another species, is another method that has been employed in the study of socialization. While some behavioural differences have been observed, these must be treated with caution. However, cross-fostering, or cross-rearing, experiments as they are sometimes called, may provide a useful method for studying **behavioural plasticity** in the

P.568

development of social behaviour. The main shortfall with both of these methods is that they do not provide an understanding of the mechanisms by which these social behaviours are acquired under 'normal' conditions (Bekoff, 1977).

Socialization period/phase

The socialization period refers to a **sensitive phase** during which animals appear most responsive to forming social **attachments** (see: **Socialization**), and its definition is a function of the natural **ecology** of the species. The temporal boundaries of the socialization phase have often been defined on the basis of **isolation** and **handling** experiments, which are not without criticism. These have led to the suggestion that it occurs between 3 and 12 weeks in the **dog** (peaking at around 8 weeks of age) but is much shorter, between 2 and 7 weeks, in the cat. This is typically followed by a **juvenile period** during which, it has been suggested, social referencing is used to a greater extent to shape perceptions of, and interactions with, the social environment, although some include this in a more extended definition of the socialization period (i.e. it is a time during which social norms are established). In addition, some define the time during which initial maternal **bonding** occurs as a period of primary socialization.

Although the bond formed with a maternal figure is in many ways unique, there is evidence to suggest that this, including the form of attachment developed at this time, plays an important role in later social development (often referred to as secondary socialization) (see: **Secure base hypothesis**). There is sometimes confusion between the socialization phase and a more extended period during which there is a greater predisposition to habituate to a range of physical stimuli in the environment (typically extending up to about 14 weeks in the dog), although the process of social relationship formation should be considered distinct from habituating to the presence of others.

Societies and animal welfare

A society is a population of human beings who share a distinctive **culture** and/or certain political institutions. More broadly, a society is an economic, social and cultural structure through which a group of people is united. One can speak about societies at different levels: compare Danish society, Western society and modern society. The word 'society' may also refer to an organized voluntary association of people for a certain cause, as, for example, in the Royal Society for the Prevention of Cruelty to Animals (**RSPCA**).

There is a growing awareness of the need to understand human relations to animals in the context of culture and other aspects of society. For example, the ranking of animals according to status, the so-called socio-zoological scale, is clearly shaped by societal values. Thus in the 19th century, when the first animal **welfare** laws were passed, the highest-ranking animals to be protected by the law were **horses** and **cattle**; **cats** and **dogs** were not covered at all. Today, the importance of cats and dogs kept as **pets** has grown and so they have, as a result, risen on the socio-zoological scale. To describe and explain this process, philosophical, sociological and historical studies are called for.

It has become clear that the notion of animal welfare, and norms governing acceptable treatment of animals, must be understood in a wider social context. This is not only so when it comes to societies and contexts differing from one's own: it is also true that one's own notion of animal welfare, and one's own standards describing good care of animals, may be enlightened by being understood in the context of one's own culture and society.

Organized voluntary associations of people who work to improve conditions for animals in human care have in the past played a very significant role in putting animal welfare on the political agenda in Northern European and in other Western countries. Over the last few decades new organizations have developed; these differ from traditional animal welfare societies in their tendency to focus on specific causes, in being run more like corporations than societies, in working at an international level and in using modern, highly professional campaigning and fundraising methods.

Sociobiology

Sociobiology is a term popularized by and often associated with **E.O. Wilson**, through his classic text *Sociobiology: the New Synthesis*, although the term was apparently first coined by the developmental geneticist John Paul Scott, who undertook the classic experiments on the **sensitive phases** for **socialization** in dogs. A key tenet of sociobiology is that **social behaviour**, along with other behaviours, has some genetic basis that can be selected for or against. The relative importance of genetic factors in different aspects of behaviour undoubtedly varies and is widely debated. At the extremes, some proponents of sociobiology lean towards genetic determinism, while some critics suggest that the complexity or nature of some traits preclude meaningful genetic **selection**. An early challenge to sociobiology focused on the development of **altruism** as a trait, whereby one individual incurs a cost to the benefit of another. It was initially thought that such a behavioural tendency would be selected against because donors would be at a disadvantage to recipients. However, these acts can be explained in terms of **inclusive fitness**, reciprocal altruism and other longer-term gains for the donor. Historically, the development of **eusociality** in insects has been used by sociobiologists to provide a particularly strong example of the implications of natural selection and inclusive fitness to explain social behaviour. In humans, sociobiological concepts have also been used to explain a range of cross-cultural behavioural tendencies, such as the taboo associated with incest and, perhaps most controversially, in the defence of human **eugenics**.

Sollwert

The term 'sollwert' is used in applied animal behaviour to refer to the desired state of an animal at a given time. Thus potential welfare concerns arise when an animal's current perceived state (**istwert**) differs from its sollwert, especially when the animal is restricted in its ability to adapt or achieve its sollwert.

Soring

Soring is the practice of applying caustic material, such as mustard oil, to the pasterns of **horses**, in particular Tennessee Walking Horses, to irritate the skin. Then chains, rollers or a series of large wooden beads are placed around the pastern so that they will abrade the burned area in order to make the lesion even more painful. The purpose is twofold: (i) to encourage the horse to shift his weight to the hindquarters; and (ii) to induce the horse to lift the fore legs higher and more quickly when executing the running walk. The hooves are allowed to grow very long, and the horse wears heavy shoes and 1 lb (450 g) bell boots.

Soring is illegal in the USA, according to the Horse Protection Act of 1970, Public law 91-540, but enforcement is weak because there are insufficient inspectors. The law is enforced by the US Department of Agriculture, which is also charged with inspection of other much larger animal populations, such as commercially bred dogs and animals in research facilities. It is not surprising that the relatively small number of Tennessee Walkers is not inspected or that lay inspectors are hired. The lay inspectors are often Tennessee Walker owners themselves and are reluctant to accuse their friends and colleagues. The citation rate for soring is much higher by USDA inspectors than by lay inspectors. Soring can be detected by the use of thermography, but this is probably not necessary because the pastern lesions are usually quite obvious.

The Tennessee Walker, originally known as the Southern Plantation Horse, is an American breed. Its original purpose was to carry a rider across a plantation in comfort while traversing long distances quickly. It was only when the horses began to appear in shows that an exaggerated running walk became desirable and soring was found to get results faster than training. Soring has also been used on jumpers to encourage them to lift their legs.

(KAH)

Sow behaviour

The European wild boar, *Sus scrofa*, is the closest living relative of today's domestic **pig** and, where free-living domestic pigs have been compared, their behaviour is essentially the same. The usual **social group** of wild sows consists of up to five adult females, probably related, and their offspring of the previous 1-2 years. Sows sleep in a simple communal nest, but may forage separately. Their natural habitat is forest, which provides both feeding opportunities and their preferred dense cover. Pigs are omnivorous, eating a wide and varied diet of both vegetable and animal matter. Dietary staples are wild fruits, nuts, acorns, roots, tubers, bulbs and seeds, as well as grasses, insects (e.g. worms, beetles and ants), small animals such as rodents, frogs, lizards, snakes, birds and birds' eggs. Pigs will also eat carcasses when given the opportunity, as well as cultivated foods such as wheat and maize. The majority of each day is spent investigating the environment and foraging. Boars are either solitary or live in small bachelor groups; they join the sow groups temporarily in autumn or early winter for mating purposes. **Oestrus** in sow groups is synchronized and breeding is seasonal, with piglets usually being born in the spring.

Wild boar are not **territorial**; instead, they form **home ranges** without well-defined boundaries, which can shift from time to time in response to food availability. The size of the home range may vary with the habitat (increasing in less plentiful areas) and the sex of the animal (being smaller in females). Home ranges calculated from radio-tracking studies have varied from 120 to over 1000 ha. Wild boar habitats are likely always to feature resting places and nests, wallows and watering places, rubbing and scratching places, rooting areas and a network of regularly used interconnecting paths. While several studies have observed wild boar to be **nocturnal**, it is probable that, in the absence of human influence, they would be diurnal, but switch to a nocturnal pattern for safety in response to disturbance and predation by humans. Farmed sows will often give birth at night, perhaps because it is quieter than during the day.

Pigs have been domesticated for at least 5000 years. Steady increases in levels of control exerted by humans over their porcine companions have culminated, in many regions of the world, in highly intensive, **confinement** agriculture, with large numbers of pigs kept in close proximity and minimal space allowance per individual. While pigs are in many ways highly adaptable, the conditions in which we keep them today are far from those they have evolved to inhabit, and this has multiple effects on their behaviour. In a farmed environment, artificial groups will be abruptly imposed, comprising single-sex, single-age, single-weight, often unrelated animals. Growing gilts are unlikely to meet a piglet until they give birth to their first litter. Mating is imposed, with no choice of sexual partner, and **parturition** may be artificially induced or augmented through injection of hormones if it is progressing too slowly.

The average duration of pregnancy is 114 days, or about four months, the majority of which the wild boar, **feral** or free-living sow will spend with her social group. Intensively farmed sows may be kept in groups that are small or large (anything from a handful of individuals to over a hundred) and static or dynamic (meaning that the group composition stays the same or changes). **Housing** may be indoors or outdoors,

P.570

and enclosure or paddock designs can vary widely. They may be bedded or unbedded, barren or enriched. Pigs are selected for rapid growth and, if allowed to eat *ad libitum*, sows may gain weight excessively, which can negatively affect milk production and impair their fertility, as well as costing farmers money. Therefore, most farmed pregnant sows are subject to severe food restriction, limiting them to a once- or twice-daily intake of concentrated feed, equivalent to approximately 60% of *ad libitum* intake, which takes only a few minutes to eat. While this precisely calculated diet contains sufficient nutrients for growth and production, it is insufficient to induce feelings of satiety. Hence it is probable that pregnant sows feel hungry most, if not all, of the time.

Feeding systems for group-housed sows have been devised to minimize **aggression** and control of **resources** by dominant individuals, ensuring that all individuals receive adequate food: these include individual feeding stalls, electronic sow feeders (which recognize individuals and allocate feed accordingly), trickle feeders (which 'tie' each sow to a single feeder by delivering food at the feeding rate of the slowest sow) and dump or spray systems that distribute feed widely on to the floor. Despite these measures, group-housed sows will fight on occasion over resources or after being mixed with unknown individuals. Gestation stalls, rectangular metal enclosures similar to the **farrowing crate**, and tethers, ties around the sow's neck or girth that confine her in one place, have all been banned in the UK since 1999, and stall use will be illegal after the fourth week of pregnancy throughout the European Union from 2013. However, stalls remain a common housing method in other regions such as North America. Gestation stalls severely restrict a sow's movement, preventing exercise and turning around, and thus violating at least one of the Farm Animal Welfare Council's **five freedoms**, the freedom to express normal behaviour. However, they also prevent fighting and simplify feeding and management, allowing large numbers of sows to be kept easily in small amounts of space.

The combination of feed restriction, lack of foraging opportunity and restrictive housing in dry sows predisposes them to develop oral **stereotypies**, which can include **bar biting**, sham chewing and licking. These behaviours may be displayed at high levels, particularly immediately after feeding. Oral stereotypies are more common in sows housed in gestation stalls, though group-housed sows will also display them, especially in barren environments. Environmental complexity - for example, the provision of space, **enrichment** or straw bedding (which can be ingested and manipulated) - can reduce the exhibition of oral stereotypy, as can the inclusion of high-bulk, low-nutrient diet additives to promote feelings of satiety.

In the free-living sow behavioural changes, including seclusion seeking and reduction in excessive movement and conflict, begin around 1 month before parturition. A few days before giving birth, the free-ranging sow leaves her group and walks up to 6.5 km to find a suitable nest site. Simple 'dummy' farrowing nests may be constructed on more than one site before the final farrowing nest is built. Nest building starts within 24 h of birth, peaks at 6-12 h before and decreases as parturition approaches, ceasing within 4 h of birth.

Nesting occurs in two phases: the exploratory phase and the nest-building phase. During the exploratory phase the sow seeks a suitable nest site. The nest-building phase consists of the sow carrying mouthfuls of bedding materials to the nest location and rooting and pawing the collected pile into a nest. In semi-natural conditions, domestic sows build farrowing nests consisting of shallow holes in the ground, rooted out and filled with grass and small branches. Survival of piglets has been noted to increase with greater distance of the farrowing nest from the group nest. The nest provides thermal and physical protection, and the sow will occupy it during birth and, with her litter, for 7-10 days afterwards. During this period she will leave the nest briefly to forage. Recognition between sow and piglets does not develop immediately after birth, but happens gradually during the period of nest occupation, equipping them to rejoin the extended family group, which they do within about 10 days of birth, but remain as an intact social unit until weaning. **Nursing**/suckling continues for at least 12-16 weeks, and **weaning** is a gradual process during which growing piglets start to forage and eat increasing amounts of solid food while still regularly, but less frequently, suckling from their mother.

Farmed sows will be transferred from gestation accommodation to farrowing quarters a few days before they are due to give birth. Outdoor sows may farrow in arcs or huts, while indoor sows are confined to pens or, commonly, a farrowing crate. In farrowing crates, domestic sows show behaviour changes (restlessness, posture changing, stereotyped bar gnawing, pawing behaviours, attempts to escape from the crate, frothing at the mouth and pupil dilation) starting about 1 day before farrowing. These behaviours share many elements and follow the same course as nest building in unrestrained sows, and may be interpreted as nest-building behaviour, frustrated and displaced by restraint. Sows may be more restless in crates than when loose-housed in pens, and their response to crating may be mediated by their accommodation during gestation, with an increased response to confinement in a crate following loose-housed gestation. Physical signs of impending parturition observed in domestic sows include swelling of the vulval lips, enlargement of the udder, **colostrum** secretion from the teats and an increase in respiratory rate.

Few published data are available on the birth process in free-living wild sows, because of the shy and cryptic nature of the wild boar and the difficulties of observing a behaviour that occurs in an enclosed nest and is performed by an animal that actively seeks seclusion. Domestic females will usually settle on their sides soon before parturition starts, a position they will remain in for the majority of the birth period. Over 90% of piglets are born with their mother lying on her side, although sows occasionally give birth lying sternally or standing up. A little straining, possibly some **vocalization**, the passage of some fluid and rapid tail swishing will immediately precede the birth of the first piglet. In between births, the sow may stand briefly and, if able to do so, turn to inspect and make nose-to-nose contact with her newborns.

Sows do not lick or groom piglets, either for cleaning, stimulation or identification, and perform little overt maternal care other than exposing their udder. Nose-to-nose contact between sow and offspring appears to be important for the establishment and maintenance of **bonding**, and free-ranging sows maintain contact with their newborns through sniffing

P.571

and grunting. Some sows, especially when giving birth for the first time, will attack newborn piglets and may kill them (**see also: Infanticide**). Even if this 'savaging' behaviour is not displayed, sows sometimes become agitated during farrowing, repeatedly alternating between standing and lying. This may be related to the discomfort of giving birth.

In domestic sows the second stage of parturition (expulsion of piglets) lasts 2.5-4.0 h, with mean inter-birth intervals of 15-16 min. The duration of parturition is similar in wild boar, although litter sizes are much smaller than in domestic sows. Although it seems logical that the length of farrowing will vary with the number of piglets, no clear relationship has been reported between litter size and duration of farrowing. There is considerable variation around this average duration, and in the length of inter-birth intervals. Piglets may be born head or rear-end first, with few complications resulting from either presentation. Piglets born towards the end of farrowing have an increased chance of being stillborn due to oxygen deprivation during the birth process. Confinement in a restrictive farrowing crate, which prevents normal pre-farrowing behaviour and constrains behaviour during farrowing, is almost certainly stressful. This **stress**, combined with lack of opportunity for exercise, may prolong the duration of farrowing, leading to increased levels of stillbirths.

Nursing (which the sow does) and suckling (which the piglets do) is much more complex in the litter-bearing pig than in species that give birth to one or two offspring at a time. During farrowing and for a few hours afterwards, colostrum is readily available from the sow's udder. Piglets locate a teat and suck soon after birth, and the nutrient- and antibody-rich colostrum is important for their survival. Once the whole litter has been born piglets will start to form a **teat order**, in which piglets consistently nurse from 'their' teat, recognizing it by smell and sight, and returning to it at each suckling bout. In order to maximize milk intake and survival, most of the litter must be present and working at each bout to elicit milk letdown.

Suckling has been characterized as comprising five phases: (i) gathering and finding teat positions (before and during which the sow may 'call' her piglets to the udder by grunting); (ii) massaging the udder; (iii) slow and steady sucking; (iv) a period of 15-20 s of rapid sucking that coincides with the sow's brief ejection of around 20 ml of milk; and (v) a return to alternating periods of massage and slow sucking after letdown (which is thought to stimulate subsequent milk production). These phases appear indistinguishable in wild boar and domestic pigs. Once a teat order has been established and colostrum has turned into mature milk, piglets will gather at their mother's udder to suckle approximately once an hour, day and night. 'Weaning' of domestic piglets consists of an abrupt separation of sow and litter, and generally takes place 2-6 weeks after birth. As little as 4-5 days afterwards the sow will be mated again.

Good **maternal behaviour** makes an important contribution to the survival of piglets in a free-ranging situation, and this is also the case in domesticated sows kept outdoors or in pens. However, sows in farrowing crates are unable to display much maternal behaviour, and production in these systems does not rely on good mothering. Thus, modern pigs are not selected for their mothering abilities, but rather for prolificacy, rapid, lean growth and docility.

In intensive European production systems, an average sow may produce 2.2 litters and up to 25 piglets per year. Litters can average 10-15 piglets (with some sows giving birth to up to 20 piglets at a time), compared with the wild boar, which will produce three to seven 'boarlets'. Farmed sows spend almost their entire adult lives either pregnant or lactating, with short breaks of only a few days after they have been separated from their piglets. Once their productivity declines, they will be sent to **slaughter**. Around 40% of sows in the average breeding herd are replaced each year, and a sow may produce four to six litters of piglets in total before being sent to slaughter around her third birthday.

Space

In terms of animal **housing**, space can be defined as that property of the environment that accommodates the interaction of the animal with the environment, that is, that accommodates its behaviour. It is a multifaceted concept that can be described either physically or functionally, and can include qualitative aspects as to how well it provides for the animal.

As a physical resource, space exists in three dimensions: length, width and height. Together, these allow space to be described in terms of a single dimension (distance), two dimensions (area) and three dimensions (volume). Examples of these uses in animal husbandry include the length of a **lying** stall (one dimension), the area of the **floor** (two dimensions) and the volume of an aviary system (three dimensions). Allometric relationships, expressing space in terms of body size, are based on body weight (BW) raised to the powers of 1/3 (distance), 2/3 (area) and 3/3 (volume). Provided the body shape and behaviour of the animals remain consistent over a weight range, the coefficients used to describe space requirements remain constant throughout that range. For example, the floor space requirement of an animal can be expressed as $\text{Area} = k \cdot \text{BW}^{2/3}$, and k will remain constant over a range of body weights.

A 'fourth' dimension of space is time. If the behaviour of animals does not need to be synchronized, then behaviour-related space can be shared over time. A large number of animals may eat sequentially from a single feeding space if feed is continuously available. However, if feed is limited, sufficient feeding spaces may be required to accommodate all of the animals simultaneously. Because most animals in a group will be resting simultaneously at some point of the day, lying space must be sufficient to accommodate the entire group, either as individual lying stalls for each animal, or a loafing area sufficient to accommodate them all.

Space requirements may be expressed as either space allowances (space/animal unit) or its reciprocal, **stocking density** (animal unit/space). For linear resources, based on distance, such as the width of a feeding space, space allowance is expressed as length/BW^{1/3}. For two-dimensional space,

P.572

such as floor area, space allowance is expressed as area/BW^{2/3} and for volumetric space, e.g. tank volume for fish, as volume/BW. If a resource is shared by several animals over time, its allocation is usually referred to by its stocking density, animals/unit (e.g. cattle/drinker).

The total space available to an animal or group of animals can be subdivided by its behavioural use. The primary uses include ingestive behaviour (eating and drinking, either together or separate locations), **elimination behaviour** and **resting behaviour**. In some conditions a portion of the space is dedicated to thermoregulatory behaviour, such as when a wallow is provided (**see: Thermoregulation**). The space required for **feeding behaviour** and **drinking behaviour** will vary with the type of feeder or drinker provided, whether feed is provided continuously or at intervals, and the time required for the animal to consume the feed and water. The time required for eating varies with the nature of the diet and the size (age) of the animal, resulting in different amounts of feeding space being required at different stages of production. Eating space may overlap completely with resting space if animals are fed on the floor.

Elimination space is somewhat determined by manurehandling systems, with bedded systems requiring additional space to accommodate sufficient bedding to absorb moisture. The remainder of the space in the pen or lot is sometimes referred to as free space. This space is used for active behaviours, including social interactions among the animals (**see: Social behaviour**). In some situations, particularly those of limited duration such as holding pens or **transport vehicles**, space is limited to the amount needed for standing or lying only.

In situations in which an animal is confined to an individual stall or uses a defined area for a particular behaviour (e.g. a free stall), the space can be seen as static and dynamic. Static space is that required physically to accommodate an animal in a particular posture. It consists of the space taken up by the body of the animal. However, animals in these situations will change postures and must have additional space to do so. Typically, an animal changing from a lying to a standing posture requires more length than that of its body to accommodate this movement. The space required to accommodate this movement is referred to as dynamic space and requires that stall dimensions be greater than the size of the animal's body in either the lying or standing posture.

Surrounding an animal is a region that the animal seeks to keep clear of other animals, called the individual distance zone or individual (personal) space (**see also: Inter-animal distance**). An animal approaching this zone may be discouraged by means of a threat, or allowed to enter if they show some type of **appeasement** behaviour. The size of this individual space will vary with the behaviour the individual is engaged in. While at rest, individual space may be non-existent, even though the same animal would enforce a zone while foraging. Some behaviours, such as grooming, require an animal to enter another's space. Social relationships may also affect the size of individual space. Dominant animals have larger zones than do subordinate, and close affiliates may be allowed to enter the zone more freely than others.

Similar to the individual distance zone is the **flight zone**, or the distance an animal allows another to approach before the animal moves away. The distance that it travels before ending its flight is the escape distance. For **group** situations, social tension will be reduced if animals are able to move about without having to enter each other's flight zone or, if they do, if they are able to flee beyond their escape distance to end the encounter.

Groups of animals, in a free-range environment, may maintain their space as either **home ranges** or territories (**see: Free-range animals; Territory**). Territories are defended against non-group members and have no overlap with other groups. Home ranges are not defended and may overlap, although the same space is rarely occupied simultaneously by both groups. Most domestic animals maintain free ranges, facilitating the management of multiple groups in a large range. However, under conditions of defensible resources, both horses and pigs have been reported to be territorial.

The quality of space refers to its ability to accommodate or enhance an animal's behaviour or welfare. Higher-quality space should better accommodate an animal's behaviour in the same amount of space, or maintain its ability to perform the behaviour in less space. Partitions or dividers in a feeder reduce **aggression** and facilitate uninterrupted eating, increasing the quality of the feeding space. Appropriate slopes and grooving in the floor can increase traction while an animal stands or lies down, increasing the quality of the space without changing its dimensions. Comfort-enhancing features such as insulated floors, freedom from draughts and walls for visual isolation also improve the quality of the space. Quality of space can also be enhanced using environmental **enrichment**.

Space is said to be adequate if animals are able to maintain normal behaviour and welfare status. Crowding refers to the impact of low space allowance (or high stocking density) on the animals, and is first evident in behavioural changes indicative of space restriction. Very low space allowance, or very high stocking densities, result in overcrowding in which the animal's welfare is impacted, as evident in severe behavioural adaptation, physiological responses, lower productivity or poor **health**.

(HWG)

Speciesism

A form of prejudice, which discriminates against members of other species and ignores their **suffering** and interests simply because they are not human. Privileging human interests for no justifiable reason other than on species lines is, according to those who use this term, tantamount to sexism and racism. The term originates from a privately printed leaflet produced by British psychologist and animal advocate **Richard Ryder** (1970).

(RA)

Spontaneous recovery

Spontaneous recovery refers to the reappearance following **extinction** of a previously learned association. Some limit the term to associations learned through **respondent conditioning** (referring to the equivalent phenomenon in relation to associations learned through instrumental conditioning as resurgence). An important implication of spontaneous recovery is that the process of extinction does not result in the permanent breaking or 'forgetting' of the previous association, but rather that it generates new learning, which may itself be lost or suppressed. In training, the phenomenon of

P.573

spontaneous recovery is important as it highlights that it is not possible to guarantee that **problem behaviour** will not re-emerge if it has been eliminated through the training of the animal.

(DSM)

Sport - use of animals

Animals can provide food, clothing, companionship and can also provide entertainment and be used for 'sport', i.e. as a source of diversion or recreation. The definition of sport is very wide, and this article refers to sport activities the reader in the northern hemisphere may not immediately associate as sport - things like bear **baiting** and **cock fighting**. Sporting use of animals can be divided into: (i) non-lethal - racing, chasing, fighting, recreational; and (ii) lethal - sport **hunting** and fishing.

In general, sport is not directly essential to human life, but *may* give added 'value' to life. The 'products of sport' - income from betting and keeping animals and animal breeding, the economic value of the animals themselves and food produced after sport hunting and fishing - can be considered as outcomes of the sporting use of animals.

If we accept the premise (and some people may not) that humans wish to be entertained, but also that animals have some basic needs - we can use this as a basis for discussions on situations where the sporting (recreation/diversion) wishes of people impact on the lives of animals. Some people may consider it a principle of animal use that the wishes of humans should not override the basic needs of the animals, and the 'benefit' to the people should 'justify' the 'cost' to the animals. (see: **Ethics**).

In many parts of the world the 'sporting' use of animals falls under general animal **welfare** legislation - but for large areas of the world there is no statutory protection for animals used in racing, fighting, baiting or as a hunted species in sport hunting. Many societies have created 'standards' by which a group or community decides to regulate its behaviour with regard to the sporting use of animals. These standards are sometimes formal - for example, in **horse** and camel racing, animals are often categorized by weight and age so that sporting competition is 'fair'. Sporting standards may also be 'cultural', or based on **seasonality** - for example, the creation of hunting seasons for sport-hunted animals in many **cultures** is based on protection of animals at mating or nesting times, or the restriction of sporting activity to a cultural group (falconry, stag hunting - once the preserve of the monarchy) reflects long-held history and distinctions of privilege. Additionally, in many cultures there are strong rituals and taboos associated with the use of animals in sport, and to prevent excess (and perhaps to prevent cruelty) some countries have made certain sporting uses of animals unlawful - cock fighting, **dog** fighting, bull and **bear** baiting, for example - but in other parts of the world these activities are still very

actively pursued and carried out in public. The following examples illustrate some of the complex issues relating to the sporting use of animals.

1. Greyhound racing, a common sport in the UK, Ireland, the USA, South Africa and Australia, and variations of dog racing found in many developing countries. The dog is expected to perform, and will be trained, fed and kept with this aim in mind. The dog may be rewarded by the physical challenges and by the bond created with the owner/trainer, it may be required to travel and be subject to intensive training, and it may also be injured during training or racing and, if the animal does not perform, or when it becomes aged, then welfare concerns - neglect, poor **housing**, poor levels of care - may develop. Rehoming or destruction of unwanted greyhounds has become a high-profile welfare issue in some countries. The owner has social links, belongs to a sporting community, and is entertained and diverted by racing, and may also derive personal reward from the contact with the dogs and may (sometimes) derive financial reward. Spectators are entertained and may make (or lose) money by placing bets on the animals, but the public is not directly exposed to the animals that do not succeed, those past their prime or those that have been injured. The regulatory authority wishes to protect human and animal welfare, and will do so only so far as the law requires and resources allow. Racehorse ownership has some parallels with sporting dog ownership and is widespread across the world, and many horses are carefully tended, often into old age. Others are kept to perform at a higher sporting level but still may become beloved companions once they retire from sport - horse-riding is a popular pastime, and owners of these recreational and **companion animals** are likely to consider the benefit (human enjoyment) versus cost (cost to horse) balance to be at least equal, or even to pan out in favour of the horse.

2. Bear baiting, particularly in Pakistan. Adult bears may have been taken from the wild, but it is more common for young animals to be taken into captivity (as they can be trained) and sometimes adults are killed during the capture of their young. The bear will experience a life of restricted **space**, with limited scope to perform 'natural' hunting, social and reproductive behaviours, and will be subjected to **injury, pain, fear** and **distress** during the fighting. The bear is usually tethered, and its teeth and claws may have been blunted. Spectators see this activity as entertainment, and there is a strong social element to attendance at bear baiting as there is to dog fighting. Money will change hands in betting over which animals will win and, additionally, the public sees an animal interaction that is likely to reinforce their view that bears are dangerous **wild animals**, and that this justifies this activity. The local authority may have the powers to prevent bear baiting - the Prevention of Cruelty to Animals Act of 1890 and the Pakistan Wildlife Act prohibit bear baiting - but a lack of political will and inadequate resourcing of policing of this activity means that it continues today in some countries.

3. Rodeos, principally in the USA, Spain, Mexico, Brazil, Australia and Canada, fiestas and bullfighting in Spain, Portugal, southern France and several countries in Latin America, roping, riding, throwing of bulls, steers and calves, and **bullfighting** all exemplify a deep-seated part of the cultural use of **cattle** in many parts of the world. The animals are usually domesticated cattle that have not been made familiar with close contact with people. In some of these activities it appears to be necessary to goad or taunt the animals to get them to 'perform', and this is carried out with hooters, gunfire or fireworks, or by the use of spears, swords or darts. In the first stages of a bullfight (*toreo*, *corrida de toros*, *corrida de touros* or *tauromaquia*) the picador stabs the muscles on the bull's neck to enrage it (to draw first blood). This is followed by the placing of the *banderillas* (sharp, short spears) on the bull's

P.574

flanks to damage the neck and flank muscles and to incite the bull to charge. During the last stages of the bullfight, the *tercio de muerte* ('the third of death'), the matador uses a cape and a sword. The matador attempts *estocada* - to stab the sword between the shoulder blades, through the thoracic inlet and into the heart. The reliability and duration of this method of **killing** is in sharp contrast to that which would be permitted under local law (in most countries) in a **slaughterhouse**.

4. Sport hunting, shooting with guns or bows, or hunting of animals using dogs, hawks or **ferrets** is widely carried out in almost all areas of the globe. The origin of these activities is clear - as a means of gathering animal food and skins. However, the scale and focus of sport hunting has shifted away from subsistence food collection in many areas and towards trophy-type hunting, where the major motivation is the killing of the animal as a demonstration of tracking, technical and armaments capability. These activities can produce food, and some proponents argue that an animal shot in the field is not subject to the **confinement** and **transport** experienced by farmed animals. **Conservation** and population number issues are widely debated in relation to hunted species, but the predominant animal welfare concerns with sport hunting are that: (i) the methods used may result in injury or distress; (ii) there is the potential for a poorly controlled means of killing (for example, when hunting with dogs); and (iii) the action of chasing or tracking may induce periods of considerable distress and fatigue in the hunted animal. There has been only a small amount of objective scientific work on the impacts of

hunting on wild animal species when compared with the literature available on, for example, farmed or **laboratory animals**.

In countries where animal welfare legislation is present and is applied in the area of animals in sport, the implementation of the law can be ineffective due to poorly designed legislation that is difficult for courts to interpret - who defines what is 'unnecessary' suffering in relation to sport? Limited resources, variable enforcement and the common finding that responsibility for enforcement is spread between government departments, so reducing coordination, may all significantly reduce the effectiveness of legislation aimed to protect animals used in sport.

Stall-walking

Stall-walking (USA), also known as box walking (UK), is the pacing of a fixed route around the stable. Typically, a circular route is traced but, in larger stables or even at pasture, horses may trace a 'figure of eight'-shaped route. Affected horses may be prompted to begin a bout of stall-walking when separated from **conspecifics**, so horses in sale yards are more likely to be detected with this behaviour than with any **feeding-related ethopathy** (behaviours not found within the **ethogram** of free-ranging members of the species). Clearly, it is not a behaviour that is possible in standing stalls (tie stalls, USA) or when a horse is in cross-ties. Evidence of this activity may take the form of a track in the bedding of a stable. Occasional stallwalkers may conduct the activity at the trot, and these are among the more likely to sweat and become exhausted as a result of the stereotypy (**see: Stereotypies**). Stall-walking must be declared at certain types of auction and tends to lower the value of affected animals. It is reported to occur in 2.2% of stabled horses.

After **weaving**, stall-walking is the most common locomotory stereotypic behaviour in horses. Both are considered similar in causation and reflect a strong association with social needs. Stall-walking is often accompanied by **vocalization** as further evidence of its being a form of barrier **frustration**. Stall-walking is reported with higher than expected frequency in horses used for endurance trials. It is possible that persistence in apparently redundant locomotory activity reflects a shift in the **endorphin** activity of horses being conditioned for stamina and resistance to dehydration. In some cases the behaviour can be eliminated by incorporating a mirror in the stable.

Concerns about the behaviour relate to the effect on the horse's ability to maintain bodyweight, as it consumes time that would otherwise be spent feeding and resting. Furthermore, stall-walking in a single direction may cause asymmetric hoof or shoe wear, and sometimes lateralized atrophy and hypertrophy of the lumbar musculature. That said, stall walkers are less likely to be isolated than horses with other stereotypies, such as **crib-biting**, because the emergence of stall-walking is not generally attributed to observational learning.

(PDM)

Star-gazing

Star-gazing describes several different behaviours: (i) the posture of **horses** that extend the neck while being ridden; (ii) an **innate** response that can reflect head, neck or chest pain; or (iii) a learned evasion of the bit. Mechanical devices such as martingales (tie-downs, USA) are frequently used to correct the posture but are undesirable as isolated remedies because they fail to address the proximal causes. Star-gazing also occurs as a **compulsive disorder** in **dogs** and as a neurological **sign**, involving extension and elevation of the neck (opisthotonus), in herbivores, most notably **sheep**.

(PDM)

Startle response

A startle response is a rapid behavioural reaction to a sudden **stimulus**. Usually, it includes immediate cessation of the previous activity and a motor reflex such as a twitch, postural tension (freezing behaviour) change, jump or **vocalization**. Startle responses may occur when the animal is exposed to a sudden noise, touch, electrical or visual stimulus and act to prepare it for fight or flight. The particular motor reflex that occurs varies between species and circumstance. The behaviour is associated with a range of neuro-hormonal changes related

P.575

to **stress**. The extent of the response, such as the length of time spent freezing, may indicate the severity of the reaction. Repeated or chronic stimulation of the startle response will have detrimental effects not only on an animal's **welfare**, but also lack of stimulation for a prolonged period, especially during development, may result in an exaggerated response or inability to cope efficiently when startled later in life (**see: Coping**).

Starvation

Starvation refers to a severe/prolonged lack of nutrients to the point of potentially threatening life. Adult birds and mammals of many species may need to lose more than 50% of normal adult weight before they die, if water is still available, although starvation is recognized as occurring long before this. Wild animals often starve as a result of prolonged adverse weather conditions, but in **captivity** animals should be buffered against these by appropriate care. It may occur in animals as a result of **disease** (causing a failure to feed, process, digest or absorb nutrients) or lack of access to nutrients in the environment. In captive animals, the latter may be a result of inappropriate management, such as having too many animals within a given system (excessive **stocking density**) or inadequate provision (failure of stockmanship), either by withholding food or providing an inadequate diet. Occasionally, starvation is a deliberate management strategy used in laying hens, which is undertaken to extend the productivity of the flock, as it induces moulting and subsequently increases **egg production** (**see: Forced moulting**).

Starvation may be associated with specific nutrient deficiency diseases (**see: Malnutrition**), but often results in more general effects, such as: (i) stunted growth in the young; (ii) loss of **libido** and shrinkage of the **gonads**; (iii) muscle wastage (as protein is used to provide energy); (iv) a fall in core body temperature and weakness (as energy is conserved); (v) anaemia; (vi) diarrhoea; or (vii) immunodeficiency.

Starving **wild animals** may not only be more willing to be approached by humans but may also more readily approach them. Supplemental **feeding** is often used to prevent wildlife from dying during periods of difficult weather, but may actually disturb the local **ecology** by skewing survival - for example, by altering the balance between species, as some are provided with supplementation and others not (this may have knock-on effects for higher predators too), or by preserving individuals that may be less well adapted to a wild existence (more tame) at the expense of others within the species, which may have otherwise had greater reproductive potential.

(DSM)

Stem cells

Stem cells are the cells that arise from the fertilized egg, or **zygote**, and which develop into an **embryo** and later into a **fetus**. At about the eight-cell stage the embryonic cells have the ability to differentiate into all tissues of the body (totipotent), but they gradually lose this ability as they further divide (pluripotent) until they differentiate into specific cell types. Research is currently aimed at trying to grow and differentiate these cells *in vitro* to replace defective cells - and even organs - in the body, and to better understand some **disease** processes.

(DBM)

Stereotypies

Stereotypies are behaviour patterns that are repetitive, invariant and have no obvious goal or function. They may consist of a single recurring behaviour, such as **bar biting** in tethered sows or **weaving** in stabled **horses**, or may involve a complex sequence of behaviour, as in one route-tracing polar **bear**, which performed a partial rearing up with an idiosyncratic head-swing at a particular spot in the enclosure on each turn. Stereotypies are sometimes confused with impulsive/compulsive behaviours. However, **compulsive disorders** involve the repetition of an inappropriate goal, whereas the **goal-directed behaviour** remains variable.

Stereotypies seem restricted to captive animals, mentally ill or disabled humans and subjects given stimulant drugs or suffering from **brain** damage. In this respect, they can be considered as **abnormal** behaviours. With respect to captive animals, however, there is controversy as to whether stereotypies represent the normal response of a normal animal to an abnormal environment (i.e. **maladaptive**) or whether they are abnormal in the sense of lacking in function and/or being the expression of an underlying pathology (i.e. malfunctional). Similarly, stereotypies in captive animals are generally considered as a sign of impaired **welfare**. However, the nature, duration and extent of the impairment have remained elusive. In the best case, stereotypies are reminiscent of earlier **frustration**, like mental scars, or may even help animals cope with adverse conditions. In the worst case, they reflect acquired brain dysfunction and/or chronic **suffering**. The answers to these questions have to be sought in the causation, the mechanisms underlying development and the effects of stereotypies on the animals themselves.

Stereotypies in captive animals do not appear suddenly in full form, but instead originate from particular behaviour patterns that become stereotypic over time. These source behaviour patterns include adjunctive behaviour, **appetitive behaviour**, **displacement behaviour**, intention movements and **redirected behaviour** (including **vacuum behaviour**); behaviour that indicates frustration, motivational conflict or thwarting. This suggests that stereotypies develop when animals are chronically or intermittently prevented from performing highly motivated behaviours or from attaining essential functional goals. Food-restricted **pigs**, for instance, develop oral stereotypies from appetitive and redirected **foraging behaviours**; gerbils denied access to a shelter develop stereotypic digging from attempts to dig a burrow; and mice develop various stereotypies from escape attempts when trapped in a barren cage. In the wild, these responses may be crucial for survival and reproductive potential. Therefore, they may be particularly resistant to **habituation** and **extinction**, which may favour stereotypy development.

However, the motivational problem underlying stereotypy development can rarely be inferred directly from the behavioural content or form of a stereotypy. Different **motivations** may

P.576

induce the same behavioural response, leading to the same stereotypy, while the same motivation may trigger alternative behavioural strategies, leading to different stereotypies. In mice, for instance, attempts to escape barren laboratory cages were found to be influenced by the motivation to return to the mother after **weaning**, to seek shelter and to explore external **odour** cues. However, while some mice attempted to escape by squeezing or gnawing through the bars of the cage top (leading to stereotypic bar-mouthing), others attempted to jump out of the cage (leading to stereotypic jumping). Furthermore, some species seem to have a very low propensity to develop stereotypies or may not develop them at all.

This is particularly puzzling in closely related species with similar **behavioural needs**, such as house mice and Norway **rats**. Their general behavioural biology is largely similar, and rats, like mice, show high levels of bar-related escape behaviours when housed in barren laboratory cages. Thus, they both seem to be faced with similar thwarting of highly motivated behaviours, in response to which they perform similar behavioural responses. Unlike in mice, however, with rats these responses do not seem to develop into stereotypies. This suggests that species differences (as well as individual differences

within species) may reflect, at least in part, differences related to the mechanisms by which behavioural responses to thwarting develop into stereotypies.

Therefore, the **causal factors** eliciting performance of potential source behaviour need to be distinguished from the mechanisms by which these behaviours develop into stereotypies. Due to the specificity of animal-environment interactions, the causal factors eliciting the source behaviour patterns from which stereotypies develop can be highly heterogeneous. In contrast, developmental changes and formal aspects of established stereotypies suggest similarities, rather than differences, in the mechanisms underlying stereotypy development.

In order for behaviour to become stereotypic, it needs to be performed repeatedly in the first place. Several factors may lead to initial repetition of behaviour. For example, constant or intermittent exposure to a stimulus will frequently elicit the corresponding response. This is particularly true when the motivation to perform that response is high and when there is little behavioural competition, due to the barren nature of the environment. For example, constant exposure of a gerbil in a barren laboratory cage to cage corners that resemble structures in the wild that would normally orient the beginning of a digging sequence readily elicits digging behaviour. When animals are frequently exposed to the same **stimulus**, the response to that stimulus often habituates. However, if a response is crucial for survival and reproductive potential in the wild, it may be highly resistant to **habituation**. In mice, for instance, habituation of escape attempts might be maladaptive because the reproductive potential of a wild **mouse** that gave up attempts to escape when trapped would be severely compromised. The same applies to hungry sows that stopped seeking food.

Once a sequence of behaviour has been initiated, repetition may be facilitated by a lack of consummation. This applies to many food-restricted farm animals, such as pregnant sows and broiler breeders. They may get stuck in an appetitive sequence of behaviour (e.g. foraging), when the behavioural response does not lead to the **perception** of a situation that correlates with the animal's expectations (e.g. satiety). And, in gerbils, a simple chamber with a tunnel-shaped entrance completely prevented the development of stereotypic digging, while the same chamber without the tunnel did not. Gerbils simply may not perceive a dark chamber as a shelter unless they experience moving into it through a narrow tunnel. This underscores just how specific the environmental **needs of animals** can be.

While specific causal factors may often explain the occurrence of particular source behaviour patterns and their repetition, they usually fail to account for the changes in form and performance typically observed in the course of stereotypy development. Three major developmental changes can be distinguished: increasing performance, increasing invariance and **emancipation**. Thus, performance of stereotypies normally increases over time, both in frequency and duration, leading to excessive performance (also referred to as overperformance) when fully developed. Excessive performance is a common feature of stereotypies, and may be the main reason for most stereotypies being detected in the first place. This may reach a point where animals do little else but **feeding**, drinking, **grooming** and resting, apart from performing their stereotypies. For example, laboratory mice may spend up to 50% of their total active time performing stereotypic bar mouthing; and polar bears were observed to perform up to 80% of their active time performing stereotypic route-tracing.

Besides the increase in performance, stereotypies will normally become increasingly *invariant*, i.e. fixed in form and orientation (also referred to as **ritualization**). In some cases, this decrease in variability of performance goes together with the loss of behavioural elements while, in other cases, additional, sometimes idiosyncratic, motor patterns are added (e.g. the head-swing in the route-tracing of the polar bear). Thus, stereotypies may become more or less complex with increasing invariance. It has been proposed that this process may also reflect response degradation, by which attempts at functional behaviour degrade into insufficient components or dysfunctional forms of that response. Together with increasing invariance, performance will normally *emancipate* from the originally eliciting circumstances. Stereotypies will thus become elicited by a wider set of stimuli or motivational states than early in development.

Stereotypies may eventually become so emancipated that they persist even in the absence of the original eliciting stimuli. This is sometimes referred to as the stereotypy becoming established or irreversible. Some consider establishment as a separate developmental change, although it might be fully explained by emancipation. Thus, with increasing emancipation, new eliciting stimuli may come to substitute entirely for the originally eliciting circumstances. In bank **voles**, for example, stereotypy performance was fully abolished by environmental **enrichment** introduced 3 months, but not 9 months, after the onset of stereotypy development, and partially abolished by enrichment introduced after 6 months.

These developmental changes indicate that there must be additional mechanisms that contribute to stereotypy development. Two alternative views have been proposed. First, stereotypies might reflect acquired behavioural strategies to cope with adverse circumstances (*coping hypothesis*). Alternatively, they might result from pathological changes at

the neural level, leading to a disruption of normal brain functioning (*pathology hypothesis*).

According to the **coping** hypothesis, stereotypies develop because of rewarding properties associated with their performance in the initial situation of conflict or thwarting. Various forms of reward could be associated with stereotypy performance, on both a physiological and a psychological level. Thus, stereotypies would act to maintain or restore, at least partially, an optimal physiological or psychological state under conditions from which the animals are unable to alter or escape by behavioural means. The coping hypothesis explicitly considers stereotypies to be responses that the animals acquire through associative learning. The rewarding consequences would act as reinforcers, thereby increasing the probability (i.e. motivation) of the same behavioural pattern being performed on subsequent occasions.

Two variants of the coping hypotheses have been examined in some detail: *self-narcotization* and *coping with stress*. The first idea was inferred from the finding that endogenous **opioids** (see: **Endorphin**) were involved in stereotypies of tethered sows. In analogy to the 'runners-high', it was speculated that animals might stereotype to narcotize themselves as a means of avoiding perception of the frustrating situation to which they are exposed. However, experimental work failed to provide supporting evidence. Alternatively, performance of stereotypies might be reinforcing for having **stress**-reducing effects. The adaptive value of such a strategy would lie in its potency to attenuate the deleterious consequences of chronic stress. Despite some correlational evidence, selective prevention of stereotypy performance in pigs and horses did not lead to the increase in stress levels predicted by the hypothesis. Furthermore, a short term increase of corticosterone levels following prevention of stereotypic bar-mouthing in mice could be explained by the disruption of familiar behavioural routines.

However, stereotypies might develop for having beneficial effects on some other, as yet unexplored, physiological or psychological system. Attempts have been made to test general predictions that are independent of the system on which stereotypy performance might act. For example, if stereotypies help animals to cope with adverse environments, animals with established stereotypies should find such environments less aversive than non-stereotypers. In bank voles, a negative relationship between stereotypy level and preference for an enriched environment seemed to support this prediction, although alternative explanations have been proposed. Alternatively, increased stereotypy performance following selective prevention, i.e. post-inhibitory rebound (see: **Rebound behaviour**), would also speak for a coping effect. Post-inhibitory rebound was found in **crib-biting** horses following prevention of crib-biting by a commercial cribbing collar. This makes sense in the light of recent evidence suggesting that crib-biting might serve to stimulate saliva release to buffer gastric acidity induced by concentrate feed, thereby preventing ulceration. However, selective prevention of stereotypic bar mouthing in laboratory mice did not lead to post-inhibitory rebound, indicating that coping may not be a general characteristic of stereotypy performance.

Adaptive models of stereotypy development compete with explanations based on maladaptive or pathological processes. Again, two slightly different hypotheses are currently being discussed: *behavioural sensitization* and *behavioural disinhibition*.

The first is based on the common assumption that stereotypies are caused by chronic conflict or thwarting of highly motivated behaviour. In response, the animals are thought to perform **appetitive behaviours** that cannot become consummatory (see: **Consummatory act**), due to the lack of a suitable goal object. The positive sensory feedback of the appetitive behaviour on the neural systems controlling it would lead to an increased probability of this behaviour being performed on subsequent occasions. In addition, progressive sensitization of the activated neural pathways would lead to emancipation of the behaviour. While the same process under normal circumstances might facilitate habit formation, it would, by coincidence, act on behaviour that would not normally be repeated over and over again, thereby leading to fixation of malfunctioning behaviour.

Indirect evidence for this hypothesis stems from studies on drug-induced stereotypies. Psychomotor stimulant drugs, such as amphetamine and apomorphine, have the potential to induce stereotypic behaviour through activation of dopaminergic systems in the brain, with the behaviour becoming more stereotyped with increasing doses of the drug. An increase in form and intensity, similar to that observed in many environmentally induced stereotypies, can also be induced by repeated administration of a constant dose, indicating behavioural sensitization to the drug. Furthermore, behavioural sensitization to the drug is also obtained by repeated exposure to various **stressors** such as mild tail pinch, inescapable foot shock, food deprivation or immobilization. During stressful experiences endogenous opioid peptides are massively released, and these have been shown to exert modulatory effects on dopaminergic pathways. Thus, stress induced by conflict or thwarting might play an important role in stereotypy development, via the sensitizing effect of endogenous opioids on **dopamine** systems in the basal ganglia. In line with this, pharmacological experiments in bank voles suggest that their stereotypies are

mediated by dopamine, and that endogenous opioids might be critically involved in the early stages of stereotypy development.

Alternatively, stereotypies might reflect impaired mechanisms of inhibitory control of behaviour (**see: Disinhibition**). Stereotypies in human mental disorder (e.g. schizophrenia, autism) and stereotypies induced by drugs (e.g. amphetamine) or brain lesions depend on reduced behavioural inhibition, possibly caused by impaired dopaminergic regulation in the dorsal basal ganglia. Impaired basal ganglia function is associated with a series of other characteristic behavioural changes, including enhanced rates of behavioural initiation, impulsivity, impaired response suppression and perseveration (e.g. in extinction tasks). In bank voles, it was recently found that stereotypic bar-mouthing correlated with increased rates of behavioural activation, hyperactivity, impairments of response timing and slower extinction learning, and that all of these signs intercorrelated. These findings suggest a single, underlying deficit that is consistent with impaired response selection caused by dorsal basal ganglia dysfunction. Thus, stereotypies might be the most apparent expression of an acquired brain pathology. On the other hand, individual variation in stereotypy performance and correlated measures

P.578

might simply reflect the normal range of variation of a population of healthy individuals. To exclude this possibility, it remains to be demonstrated that these signs change together as stereotypy develops, and back again when the stereotypy is cured, e.g. by environmental enrichment.

Despite decades of extensive research, our understanding of the causal factors and mechanisms underlying stereotypy development has remained elusive. Because the welfare implications of stereotypies clearly depend on these aspects, no definitive assessment can be made. Present evidence suggests that stereotypies are unlikely to be learned responses for coping with environmental adversity. Although they all seem to develop from attempts to cope with behavioural thwarting, they are likely to reflect true behavioural disorders based on some form of **central nervous system (CNS)** dysfunction, at least in their fully established form. Stereotypies are clearly heterogeneous in causation, yet the similarities in development indicate common underlying neural changes. Even if they reflect CNS dysfunction, the question still remains as to how such dysfunction is perceived by animals. It was proposed that stereotypies become 'hardwired' with establishment, thereby losing emotional significance.

However, in the absence of a coping effect, the problems that gave rise to stereotypy development might persist to be perceived as **aversive**. Others consider stereotypy performance to be a direct sign of animal suffering caused by the '**boredom**' induced by a lack of control over the environment. While this hypothesis has remained vague and has not produced testable predictions, others have stressed the possibility that stereotyping animals might become frustrated about their increasing inability to put knowledge into action, based on evidence for an action-knowledge dissociation associated with impaired inhibitory control, as also observed in human patients. Since all of these hypotheses are essentially speculative, identifying the emotional correlate of stereotypy performance is likely to remain a major challenge in the near future.

Steroid hormones

The steroid hormones are characterized by a series of three joined 6-carbon rings fused with a fourth 5-carbon ring. They constitute a large endocrine family synthesized by the **gonads** and by the **adrenal glands**, with their function varying according to the functional groups attached to these rings. Steroids include the sex hormones: **androgens (see also: Testosterone)**, **oestrogens** and progestagens (**see: Progesterone**), and two important homeostatic regulatory hormones, the **glucocorticoids** and mineralocorticoids (**see: Corticosteroids**).

The lipid basis of the molecules means that they are able to pass freely across membranes and, as a consequence, cannot be stored within vesicles in their producing cells, and so are not available for instantaneous release in the same way that

the peptide hormones are, but must be synthesized on demand. Membrane permeability also means that they are not limited to activating cell surface receptors, but can bind to intracellular receptors and frequently have direct effects on their target cell's DNA via nuclear receptors. Their hydrophobic nature results in steroid hormones often being associated with specific binding proteins for transport in the aqueous plasma, and thus active hormone levels can be influenced not only by the level of release but also by the amount of available binding protein, which affects the proportions of bound and free hormone within any system.

Breakdown and removal of steroid hormones is also a more complex process than for peptide hormones, involving catabolism in the liver. Taken together, the biophysical properties of the steroid hormones mean that they are frequently involved in regulation of long-term and sloweracting development and behavioural effects with a relatively slow response time and a long half-life, although they are also capable of initiating rapid, acute responses in some circumstances, e.g. in relation to the **stress** response.

(MRC)

Stimulus

In broad terms, a stimulus is any factor or event that elicits a response. A stimulus-response system is observable at any biological level, from genes and cells to organisms, **social groups** and **ecosystems**.

(BM)

See also: Stimulus-response behaviour

Stimulus-response behaviour

Early ethologists and behaviourists devoted much attention to stimulus-response systems. These systems are expected to be relatively stable and fixed for **instinctive behaviours** and/or for basic survival needs (e.g. avoidance of danger). The factors affecting stimulus-response systems, and how the link between a particular **stimulus** and a behavioural response may be modified by experience, have been the topic of various learning theories (**see: Conditioning - types of**).

Stocking density

Stocking density is the ratio of animal units to space. The units are often based on body weight (BW) and should be expressed in appropriate terms for the type of space provided. For space measured in distance, the most appropriate term would be $BW^{1/3}/\text{length}$; for area, $BW^{2/3}/\text{area}$; and for volume, BW/volume . In the case of a **resource** used by one animal at a time (point source), such as a defined feeder space or a drinker, stocking density can be expressed as animals/unit (e.g. pigs/feeder space). Some literature uses 'stocking density' to refer to animals/pen, but this confounds **group** size and true stocking density. The appropriate term would be $BW^{2/3}/\text{area}$. Stocking density is the reciprocal of space allowances. Crowding refers to the impact of high stocking density on animals, and is first evident in behavioural changes indicative

P.579

of space restriction. Very high stocking densities result in overcrowding in which the animals' **welfare** is impacted, as evident in severe behavioural adaptation, physiological responses, lower productivity or poor **health**.

Stockperson

With increasing **intensification of animal production (see: Farming of animals)**, the dependency of livestock on the stockperson to effectively care for and manage them correspondingly increases. While all forms of livestock production rely to varying degrees on key inputs from the stockperson, this reliance is arguably greater with increased confinement of the animal.

The key feature of any employee, irrespective of the industry in which he or she works, is how well he or she does the job. Delving further, work performance is predominantly affected by three interrelated factors: capacity, opportunity and willingness to do the job. Therefore, in considering the work performance of the stockperson in a livestock industry, capacity includes characteristics of the person such as technical skills and **knowledge**, and attitude and behaviour towards the animals, while willingness includes **motivation**, job satisfaction and work attitude, and opportunity includes working conditions and facilities, actions of co-workers and organizational policies and rules. In order to optimize the role of the stockperson in animal productivity and welfare, an understanding of the impact and regulation of the work performance of the stockperson is necessary.

Capacity

Technical skills and knowledge

Knowing and being skilled at the techniques that must be used to accomplish a task are clearly prerequisites to being able to perform that task. Thus, these job-related characteristics will be the most limiting factors to job performance in situations where specific technical skills and knowledge are required to perform the tasks. While there are few data in agricultural industries, this basic premise is nevertheless universally accepted.

Some of the key characteristics of stockpeople include a basic knowledge of both the behaviour of the animal and its nutritional, climatic, **housing**, health, social and sexual requirements, together with a range of well-developed husbandry skills and knowledge to effectively care for and manage farm animals. For instance, stockpeople may have knowledge and skills in a number of diverse management and husbandry tasks such as: (i) **oestrus** detection and mating assistance; (ii) semen collection and preparation and **artificial insemination**; (iii) pregnancy diagnosis with ultrasonography; (iv) artificial rearing of early-weaned animals; (v) milk harvesting; (vi) controlling and monitoring feed intake for optimizing growth, body composition, milk production and reproductive performance; (vii) pasture management for optimizing pasture production; (viii) routine health checks; (ix) monitoring and adjusting climatic conditions in indoor units; (x) administering antibiotics and vaccines; (xi) **shearing** and crutching **sheep**; (xii) teeth and tail clipping of piglets; (xiii) **castration** of males; and (xiv) effective and safe animal **handling**. These are all skilled tasks, and stockpeople are required to be competent in many of these tasks.

Attitudes and behaviour towards animals

Fear is generally considered an undesirable emotional state of **suffering** in both humans and animals. While fear thresholds have been reduced by **domestication**, fear responses have not been eliminated from domestic animals. There is substantial variation between commercial farms in animals' fear of humans and, furthermore, there are significant sequential relationships between the stockperson's attitudes and behaviour towards their animals and the fear of humans and productivity of farm animals.

Studies in both the dairy and pork industries have shown that negative attitudes of stockpeople towards handling their animals are correlated with a high percentage of negative behaviours by stockpeople in handling their animals, which in turn is correlated with high fear levels and low productivity in these animals. Negative attitudes of stockpeople towards handling include beliefs that considerable verbal and physical effort is required to move their animals and that these animals do not require **petting** and stroking. These are correlated with a high percentage of negative behaviours used by stockpeople in handling their animals. Negative behaviours used by stockpeople include not only forceful hits and slaps, but also audible slaps, pushes, shouting, fast speed of movement and sudden movement.

In contrast, positive behaviours include pats, strokes, the hand of the stockperson resting on the back or flank of the animal, talking and slow deliberate movement. The sensitivity of dairy cows and **pigs** to human behaviour is highlighted by the impact of moderate negative interactions, such as audible slaps, pushes, shouting, fast speed of movement and sudden movement by humans, something that is not intuitively obvious to most of us. Similar effects of human-animal interactions have been found in the poultry industries. Laboratory studies indicate that the likely mechanism responsible for the adverse effects of high fear on animal productivity is via a chronic **stress** response and its consequences. There is also evidence in

the dairy and pork industries that human-animal interactions may directly affect a number of job-related variables, such as job satisfaction.

The attitude of the stockperson towards interacting with his or her animals is obviously a key antecedent of the behaviour of the stockperson, which in turn is an important determinant of the animal's fear of humans. The existence and importance of these sequential relationships are demonstrated in intervention studies in both the dairy and pork industries, in which cognitive-behavioural training of stockpeople, designed specifically to improve these key attitudes and behaviours of stockpeople, decreased animal fear and improved both animal productivity and welfare.

The development of fear responses in livestock is not surprising, considering that stockperson interactions may be biased towards negative ones. Opportunities for positive human contact are probably reduced in modern production units, and many routine husbandry tasks undertaken by stockpeople may contain **aversive** elements. This bias towards negative interactions, together with the sensitivity of farm animals to even moderate negative interactions, highlights the

P.580

challenge confronting stockpeople in improving their interactions with farm animals and emphasizes the importance of training.

Willingness

While the impact of these other characteristics may be obvious, they have been less researched in the livestock industries than the impact of the stockperson's attitudes and behaviour.

Job motivation and commitment

It is convenient to group these two attributes together, as they together refer to the extent to which a person applies his or her skills and knowledge to the management of the animals under his or her care (e.g. how reliable, thorough, conscientious, etc. a person is). Factors such as job satisfaction, meaningfulness of work, utilization of skills, etc. will affect work motivation and commitment. High job performance in any industry relies on a combination of motivation, technical knowledge and skills and an opportunity to perform the job. Clearly, low motivation will limit job performance regardless of technical skills and knowledge of the individual. For example, while an ability to identify any departures in the behaviour, health or performance of the animal is an important technical knowledge and skill, the willingness to regularly inspect animals and to promptly provide or seek appropriate support to address any departures is obviously critical in achieving high animal productivity and welfare.

There are various theories on how work conditions may affect job satisfaction and work motivation. For example, motivation to perform tasks will improve with rewards such as feelings of pride or accomplishment. In fact, a hierarchy of needs may influence motivation, with esteem needs (recognition by others) and self-actualization (self-fulfilment) motivating workers once the physical, safety and social needs of the individual have been met.

Job satisfaction

This factor is influential because of its indirect effects on work performance: job satisfaction will directly affect other job-related characteristics such as job motivation and commitment, motivation to learn new skills and knowledge and thus, in turn, technical skills and knowledge, etc. Job satisfaction refers to the extent to which a person reacts favourably or unfavourably to his or her work and is considered to derive from the extent to which a person's needs or expectations are being met by the job.

As mentioned above, it is generally considered that job satisfaction is influenced by rewards (personal and financial), job design and enrichment (e.g. involvement in decision-making processes), work performance, animal comfort and **health** and the working environment. As with some of the above job-related characteristics, there is little evidence in the agricultural industries that job satisfaction affects animal productivity. However, it is generally recognized that job performance in any industry is influenced by job satisfaction via its effects on job motivation and commitment, motivation to learn new skills and knowledge, etc. Several authors have suggested that a decline in job satisfaction is associated with staff turnover and absenteeism.

Personality

Although there is some disagreement among psychologists, a **personality** trait is generally considered to be a relatively enduring characteristic that exerts a general effect on the individual's behaviour and, while personality cannot be observed

directly, it can be inferred from the person's behaviour. Most researchers agree that personality can be characterized in terms of the 'big five' personality traits: 'extraversion/introversion', 'emotional stability', 'agreeableness', 'conscientiousness' and 'intellect'. Furthermore, it is also generally well accepted that personality factors may be useful in matching people to some kinds of jobs. For example, discipline and conformity may be important factors in some jobs in which routine tasks are performed by teams of people, while independence, introversion and self-motivation may be important in others in which the tasks are more problematic and where the individual may at times work alone. Indeed, there is some limited evidence to support the importance of personality factors in the livestock industries.

Research on stockpeople in the pork industry has shown that the importance of personality factors on piglet survival may vary according to the working place, with the relative importance of the traits depending on the type of farm. Selfdiscipline was a trait that appeared to be important at all farms studied; however, high insecurity and low sensitivity were favourable traits in relation to piglet survival at small, independent owner-operated farms, while stockpeople that were highly reserved and bold, suspicious, tense and changeable were associated with higher piglet mortality at large, integrated farms.

While an early study in the dairy industry indicated that the highest-yielding herds were associated with stockpeople who were introverted and confident, recent research found that personality factors, based on similar measures used in the earlier study, were not significantly correlated with cow productivity. However, this recent study found that some personality factors were significantly correlated with the attitudes of stockpeople. Agreeableness, which is one of the 'big five' personality traits and is generally considered to be associated with cooperation, good nature and tolerance in a person, correlated positively with a positive attitude towards cows. Agreeableness also correlated positively with the use of positive behaviours and tended to correlate negatively with the percentage of negative behaviours.

These results support the general view in the current literature that personality factors may influence stockperson performance in ways that are relevant to animal productivity and welfare.

Empathy

Several authors have suggested that the degree of empathy may predispose people to be good stockpeople. Empathy can be described as the capacity to put oneself in the place of another, and stockpeople may therefore perform better if they have a good insight into the emotional responses of the animals under their care. There is limited evidence in the dairy and pork industries to suggest that empathy may be a factor underlying the development of positive attitudes towards pigs: empathy towards animals was positively associated with positive attitudes both about animals and towards interacting with animals.

P.581

Opportunities

There is a clear need to identify the attributes that best allow a person to meet the job requirements of a stockperson. These characteristics will be a combination of learned factors, such as attitudes, handling and observational skills and technical knowledge, and dispositions, such as personality and empathy.

The sequential relationships between stockperson attitude and behaviour and animal fear, welfare and productivity demonstrate the opportunities to improve animal welfare and productivity by appropriate selection and training of stockpeople. Other job-related characteristics such as technical skills and knowledge and job motivation and commitment should also be targeted in the selection and training of stockpeople. A number of recent studies in the dairy and pork industries demonstrate excellent opportunities to improve animal welfare and productivity through training and selection of stockpeople.

While there is little evidence in the livestock industries relating personality and empathy directly to work performance of the stockperson, these characteristics may have indirect effects on animal welfare and productivity. For example, the antecedents of attitudes are many and varied. Experience, demographic variables, various general attitudes and personality traits may indirectly affect behaviour through their influence on attitudes and thus these characteristics, such as personality and empathy, may operate indirectly through attitudes. Furthermore, personality traits may be useful in matching people with specific jobs in the livestock industries. For instance, as stated above, independence, introversion and self-motivation may be important factors in which the tasks are more problematic and where the individual may at times work alone.

Therefore, there is a clear need to reduce the limitations that human-animal interactions impose on the welfare and productivity of commercial farm animals. While our understanding of the regulation and impact of human-animal

interactions has improved considerably over the last decade or so, recognition of the role of stockpeople in the welfare and productivity of livestock has only recently occurred.

Traditionally, stockpeople in modern animal agriculture have been regarded as unskilled labourers. The role of stockpeople as the key people responsible for the day-to-day welfare and productivity of the animals under their care has not received due acknowledgment, even though the welfare and productivity of large numbers of animals are entrusted to the care of these stockpeople. Much has been done to improve genetics, nutrition, health and housing of livestock, but efforts to target stockpeople, who perform such a key function, have just begun.

It is likely in the near future that the general public, consumers, governments and the livestock industries will place an increasing emphasis on ensuring the competency of stockpeople to manage the welfare of farm animals; this is likely to occur in both intensive and extensive animal industries. Appropriate strategies to recruit and train stockpeople in the livestock industries will be integral in safeguarding the welfare and productivity of commercial farm animals.

Stone-chewing

Picking stones up into the mouth and chewing them has been commonly reported in **pigs**, and also in **dogs**. It has variously been described as **play** behaviour, redirected **foraging behaviour** or a stereotypic behaviour (**see: Stereotypies**). In pigs, stone-chewing is often observed in sows housed on paddocks, and most frequently on paddocks where plant cover has been removed. The major issues surrounding stone-chewing involve speculation as to its cause and/or function and potential **health** problems that it may cause the animal in chewing or swallowing the stones.

Horrell and A'Ness (1999) observed wild boar in a seminatural environment and commercial pigs in six different environments. They reported that commercial sows housed on arable land and housed indoors in small straw yards with stones available spent 46.5 and 40% of observation time, respectively, chewing stones, which was 10-20% more than sows in three grass-based paddock treatments. Wild boar spent less than 1% of their time chewing stones in their enriched environment. Dailey and McGlone (1997) reported that sows on pasture chewed grass, sows in crates chewed the metal bars of the crates and sows on a soil-covered paddock chewed stones to a similar extent. Both sets of authors conclude that stone-chewing represents thwarted foraging behaviour and may be a form of stereotypic behaviour, as it is most prevalent in relatively barren environments of bare-earth paddocks. Horrell and A'Ness (1999) hypothesize that it is a function of **boredom** or a **coping** response to **stress**.

In terms of health concerns, Davies *et al.* (2001) examined teeth and stomach contents of indoor- and outdoor-housed sows and found that tooth damage (30 and 28%, respectively) and wear (91 and 88%, respectively) were in fact very similar in both populations and thus independent of stone-chewing, which was only available to outdoor-housed sows. Even though nearly 40% of outdoor-housed sows had stones in their stomachs, there was no indication that stone-chewing affected the physical health of the sows.

Stray voltage

Animals can be affected by stray voltage in their housed environment, particularly if it is a wet environment and the building is inadequately earthed. This has been detected in cattle, which can readily detect the low-level electric currents that often exist in parlours where the wet environment and connection of machinery to their udder makes them particularly susceptible. Most cows will respond behaviourally to a 3 mA current of 0.7 V, and some will respond to a 1 mA current of 0.2 V. The resistance to the passage of electricity is only about 250-400 Ω , as a result of their direct contact with the floor at four points. The resistance provided by humans is two to ten times greater, depending on footwear, etc. At low levels of current, typically **heart rate** is slightly elevated, and this increases with the current together with the appearance of overt behavioural responses. Mild behavioural responses include flinching and **vocalization**, progressing to a startled response and **avoidance behaviour**. In terms of voltage, about 1-2 V will elicit a response from the majority of cows, and it is recommended that stray voltage should be less than 0.35 V, which will be perceived by less than 10% of cows.

Stray electricity may also derive from off-farm sources, in particular where there are three-phase supplies nearby. It can be caused by: (i) large voltage drops on the farm, which cause the resultant supply to be out of phase with the central supply; or (ii) faulty equipment grounding, especially in a corrosive environment. Electricity can be used on the farm to control the movement of animals, for example into the milking parlour by electronic crowd gates, in front of self-feed silage where an electrified bar may be used, by electric fences or by using electrified training devices. All of these may produce stray electricity if not properly earthed. Intermittent, irregular shocks are more harmful than continuous stimulation, due to greater difficulty in **habituation**. If the stray electricity is present in a water trough, animals may lap at the water like a dog rather than immersing their muzzle in the water.

(CJCP)

Stress

The word 'stress' brings with it the connotation of a negative state; however, stress is a normal biological state that every living being experiences. Not all stress is negative or **aversive**. For this reason the term has been broadened to include stress, **distress**, which is negative stress, and **eustress**, which is positive stress. Under these categories, stress can be used to designate everyday challenges to **homeostasis** with which an animal is able to effectively cope, without causing negative welfare. Eustress is stress that is positive, such as stress due to wilful exercise, **play** behaviour, **reproductive behaviour** and 'thrill-seeking' behaviour, as seen in humans. Distress then is used to refer to stress that does have a negative impact on animal welfare. The challenge provided to scientists and producers is being able to distinguish when an animal is being stressed to the point of impaired welfare and determining how to eliminate this stress.

The concept of stress has been studied for around 100 years. Much has been learned but many more questions remain to be answered. The general definition of stress itself is often debated. Moberg (2000) defines stress as 'the biological response elicited when an individual perceives a threat to its homeostasis'. He goes on to state that 'When the stress response truly threatens the animal's **well-being**, then the animal experiences "distress"'. Similarly, Charmandari *et al.* (2005) define stress as 'a state of threatened or perceived as threatened homeostasis'. In contrast, Broom (2001) defines stress as 'an environmental effect on an individual which overtaxes its control systems and results in adverse consequences, eventually reduced **fitness**'. Biological fitness is commonly measured by the ability of an animal to produce offspring that make up

future generations. Thus, Broom's definition judges welfare to be poor if fitness is reduced, as opposed to Moberg's and Charmandari's definitions, which allow for less profound experiences, which may not reduce reproductive ability, to be classified as stress.

The idea that is common in almost all definitions of stress is that an animal must make changes, behavioural and/or physiological, to respond to the **stressor**. Furthermore, that if the changes are profound enough, the stress is considered deleterious, often termed 'distress'. It may be useful to think of the concept of stress relative to engineering standards. A load-bearing beam in a home has a considerable amount of weight challenging its integrity. However, it is not until the weight becomes so great that the beam may break that we are concerned about the stress placed on the beam. Animals are, of course, not inanimate objects, and our concern extends prior to the point of 'breaking' the animal. It is this challenge, deciding when the stress is merely 'stimulation' or 'distress', which occupies a great deal of research effort in the study of stress. The complexities are further detailed by the realization that animals are not identical beings and that each can experience stress in its unique manner. Previous experience, social setting, mood and **health** can all alter the level of stress an animal experiences.

The duration of time over which an animal experiences stress is important as to whether the stress causes deleterious effects. Often, an animal can experience short-term (acute) stress and suffer few, if any, long-term effects to its health or productivity. For example, animals are often restrained during which time they make enormous attempts to escape and exhibit elevations of **heart rate**, **blood pressure**, **epinephrine**, **norepinephrine** and cortisol - all classic indicators of a stress response. Almost all stress researchers would consider such an animal to be experiencing 'distress'. However, once the animal is released, behaviour will quickly return to normal, along with physiological indicators of stress. In this situation, there is little chance that a long-term deleterious effect will be experienced by the animal. In contrast, chronic stress (long term) can have profound deleterious effects. For example, animals housed at very high **stocking density** or with very aggressive **conspecifics** have been shown to have reduced growth and/or reproductive ability. It is also well established that chronic stress impairs normal immune function. Thus, the ability of an animal to escape a stressor, and thus relieve its state of stress, is critical to maintenance of its well-being. This concept is important, because many situations in animal husbandry do not allow animals to control their exposure to stressors.

P.583

In order to maintain homeostasis and respond to stressors, animals make both behavioural and physiological adjustments. To respond to stressors that pose both a psychological and physical threat, such as a predator, animals respond by fighting or fleeing. Obviously, the behavioural component of the response is to fight or flee. The physiological response is characterized by elevations in heart rate, stroke volume, blood pressure and mobilization of glucose. These changes in physiology allow the animal to meet its needs of moving oxygen to the muscles and **brain**, and supplying the body with energy in the form of glucose to mount the behavioural response.

All of these responses are adaptive in the sense that they provide the opportunity for the animal to successfully cope with the predator. This brings up an important point: the state of being stressed is a normal, purposeful condition that allows species to survive. Common usage of the term 'stress' conveys a negative connotation and implication that all stress should be eliminated. This is not the case. The stress response is a normal function of the body, just like sweating in response to excessive heat. Sweating allows the body to return its temperature to normal levels. Activation of the stress response also allows the body to return to its normal state. The problem arises when the stress response is so profound or of such a long duration that the health of the animal is threatened.

When such profound activation of the stress response occurs, deleterious effects to both physical and psychological health can occur. Physically, animals subjected to unrelieved stress can have an impaired **immune system**. This impairment permits infections from bacteria and viruses to make the animal sick. Furthermore, typical hormones often highlighted in the stress response, such as **glucocorticoids**, can have negative effects on many other physiological systems. For instance, glucocorticoids are known to suppress **luteinizing hormone (LH)**, which results in suppression of reproductive function. Glucocorticoids are also known to suppress **insulin-like growth factor**, which results in suppressed growth. See Lay and Wilson (2004) and Charmandari *et al.* (2005) for a more comprehensive review of the negative impact of stress on health and productivity. Psychologically, animals subjected to unrelieved stress can experience states similar to **anxiety** and **depression**, as observed in humans. However, due to the subjectivity of these states, very little is understood about their intricacies. Dantzer (1994) provides a comprehensive review of subjective states and their importance to the animal's experience of stress.

An animal's reaction to exposure to a stressor is also dependent upon the type of stressor. Stressors can be physical, environmental, nutritional, metabolic or psychological. In general, almost all physical stressors cause the animal to

experience some type of psychological stress. It is often difficult or impossible to separate which reactions are due to the physical stressor and which are due to the psychological stressor. For instance, an animal that is being chased by a predator has physiological responses indicative of the physical stress of running; however, these responses are also indicative of a fear response. In cases such as these, some physiological responses could be maximum, such as heart rate, while others could be additive, such as an increase in cortisol, which is further increased by the feeling of fear.

Some stressors are of an entirely psychological nature. This is often the case when an animal is fearful. Poultry can exhibit a phenomenon termed '**fowl hysteria**', which is characterized by a stimulus, such as a door slamming, causing the flock to act as if panicked. Research has consistently shown that a psychological stressor is more potent in causing harm as compared with a physical stressor. Some stressors are due to environmental effects. Extremes in temperature and air quality are common environmental stressors. These types of stressors typically do not invoke a psychological stress response. However, these are significant stressors in terms of animal welfare with chronic exposure to either able to cause **death or disease**.

Nutritional and metabolic stressors also exist that push the animal past its ability to maintain homeostasis. In production agriculture, demands for high productivity require that nutrients be obtained and utilized at a rate in order to maintain a positive net energy balance. However, situations of high productivity, such as a dairy cow that produces great quantities of milk, a hen that produces many eggs or a sow that produces very large litters, can stress some individual animals to the point that their welfare is poor. Measures of poor welfare in these situations are illustrated by dairy cows that do not conceive, hens that have sequestered so much calcium from their bones to lay eggs that their bones easily break, and sows that emerge from **lactation** with little body fat and develop body sores from lying on hard surfaces.

Measures of productivity are often used to help determine whether an animal is being subjected to significant stress. In livestock production systems, productivity for an animal is characterized by measures of growth and function of the reproductive system, such as the production of eggs, offspring and milk. In many ways, these measures are very useful. Exposure to a chronic stressor activates physiological systems that have the ability to impair, disrupt and suppress the above measures of productivity. Thus, if an animal is being exposed to a stressor and these measures of productivity are negatively affected, the animal is in a state of distress.

However, there are several problems with using productivity as an indication of distress. First, productivity that is lower than expected can be due to causes other than stress. For instance, genetics play a large role in all aspects of productivity, and an unstressed animal may have low productivity simply due to its genetic make-up. Non-stressful environmental factors also play a role in productivity. For instance, the length of light exposure can decrease egg production as well as changes in diet, neither of which are necessarily stressful to a hen. Secondly, many stressors are not so severe as to decrease productivity but are still a welfare concern. Transportation stress is of significant concern, yet this stress does little to affect reproductive status or growth of most animals (**see: Transport**).

If a stressor does decrease productivity, it can be considered a severe stressor. Another problem with using productivity as a measure of stress is in determining the timespan to consider. Often, animals produce at a very high level, but have shorter life expectancy due to their high level of productivity. In this situation, life productivity is low, while weekly productivity may be high. Also of consideration is the problem of determining what is 'normal' productivity. Without a normal, or 'gold standard', we cannot say whether productivity is high or low. Using the herd average as the standard represents

P.584

flawed logic, because the entire herd could be stressed. Thus, lacking a legitimate standard, productivity has limited value as a measure of stress.

The question then remains: what measures should be used to quantify stress? Given the current state of knowledge, the best approach is to collect a wide array of information, including: physiology, behaviour, productivity, cognitive state and measures of subjective states. None of this information will be a perfect measure by itself but, viewed together, can provide insight as to the animal's state of stress. Although we have learned a great deal about stress from previous research, much more needs to be learned before simple quantitative assessments can be recommended.

Stress hormones

Stress hormones are those hormones whose concentrations are considered to be altered, either increased or decreased, when an animal is exposed to a **stressor**. An animal's physiological response to **stress** concentrates on meeting its needs for the 'fight or flight' response. Toward this end, hormones are altered in order to: (i) change blood flow so that blood is directed toward those tissues such as skeletal and cardiac muscle and away from 'non-essential' tissues such as the gastrointestinal tract; (ii) increase energy by creating and liberating glucose; and (iii) cause lipolysis to liberate free fatty acids from fat as an energy source to be used in the response. Thus, the main stress hormones have been considered to be **glucocorticoids** (predominantly cortisol and corticosterone), **epinephrine** (a neurohormone, also known as adrenaline) and **norepinephrine** (a neurotransmitter, also known as noradrenaline).

The challenge in defining a single or class of 'stress hormones' is that the hormones and neurotransmitters currently used are all non-specific to the stress response. Each of those listed have base functions in the body to maintain **homeostasis** and, thus, are present and measurable even when an animal is not stressed. The reason they have been commonly referred to as stress hormones is because, when an animal is challenged with an aversive stimulus, the levels of these hormones and neurotransmitters are increased. However, these same compounds' levels are also increased when animals experience states not considered to be stressful, such as exercise and copulation.

Along with these traditional hormones listed above, stress research has also measured a variety of other hormones when assessing stress in animals. Traditional stress hormones cause a wide variety of effects in the body, and thus they also alter many other hormones and compounds, which have been used to assess stress in animals. For instance, it is well known that glucocorticoids inhibit **luteinizing hormone** (LH), which has allowed researchers to use LH as a measure of stress in animals. Similarly, glucocorticoids also inhibit **insulin-like growth factor-1** (IGF-1), which has allowed its successful use in measuring stress as well.

Stressor

A stressor is anything that induces a **stress** response. Use of the term has been advocated as it helps to differentiate linguistically the **stimulus** causing the response from the actual response, both of which are sometimes (somewhat confusingly) referred to as 'stress', e.g. the mixing of unfamiliar animals is a stress for them (stimulus) and the mixing of unfamiliar animals is a cause of stress (response).

(DSM)

Stroke volume

The stroke volume is the amount of blood pumped from the left ventricle in a single heartbeat, and is measured in ml/beat. The stroke volume can be calculated using the formula: $SV = EDV - ESV$, where EDV is end-diastolic volume and ESV is end-systolic volume. It is not, therefore, the total volume of blood that the ventricle can hold, but just that portion that is ejected during ventricular contraction. The stroke volume can be influenced by the physical size of the heart, the contractility of the cardiac muscle (i.e. the intrinsic ability of a cardiac muscle fibre to contract at a given fibre length), duration of contraction, the preload (i.e. the amount of ventricular stretching prior to contraction) and the afterload (i.e. the pressure that the ventricular cardiac muscle has to generate to eject blood into the aorta).

In general, stroke volume will increase with increasing heart size, increasing duration of contraction, increased contractility in response to positive inotropic compounds such as **catecholamines**, increasing preload and decreasing afterload. Stroke volume will decrease with decreasing heart size, decreasing duration of contraction, decreased contractility in response to negative inotropic compounds such as **beta-blockers**, decreasing preload and increasing afterload. Responses to acute challenges often result in linear increases in **heart rate**, but the changes in stroke volume may be quite different and dependent on the characteristics of the individual. For example, exposure to a sudden **stressor** may stimulate the sympathetic-adrenal-medullary axis, resulting in catecholamine release, which will increase contractility - i.e. have a positive effect on SV. However, catecholamines also increase **blood pressure**, which will increase afterload - i.e. have a negative effect on SV.

(RM-F)

Stunning

Stunning refers to the process whereby an animal is rendered insensible, which is normally required by law in **slaughterhouses** prior to **slaughter**, in order to reduce the **suffering** caused by the slower exsanguination **killing**

P.585

procedure that leads to the **death** of the animal. Stunning may be undertaken in one of a variety of ways, depending on the species. Electrical stunning is commonly used in **pigs** and poultry (with **cattle** being stunned in electric boxes in some countries), but the **restraint** and **handling** prior to stunning can result in **distress**. Gaseous stunning is also used commercially for both pigs and poultry, and usually involves high levels of carbon dioxide (which many animals appear to find **aversive**) or inert gas such as argon (which appears to be less detectable by the animals). In many countries, cattle are normally stunned by physical percussion (**captive bolt**).

Some **religious slaughter** procedures have been criticized on animal **welfare** grounds, as they are often interpreted as requiring the animal to be fully conscious during the procedure. It has been argued that the original aim of these customs was to minimize suffering and provide a 'respectful' death, and therefore they need to be revised to ensure that suffering is minimized rather than the procedure adhered to for its own sake. For this reason, some religious leaders allow stunning prior to slaughter.

Subclinical

A subclinical condition is one that is present within an animal but not overtly manifested or detectable by routine physical or laboratory examination procedures. As such, it is not in itself normally an immediate **welfare** problem, but is of importance to animal welfare. A subclinical condition may make an animal more prone to a clinical manifestation of the problem that does cause suffering, e.g. a racehorse with a subclinical **lameness** may be at greater risk of a more catastrophic **injury** if it is raced, or predispose an animal to other problems, e.g. an animal with a subclinical infection may be immunocompromised and so prone to a range of other infections.

By definition, subclinical conditions are difficult to detect and so their true significance in animal welfare often remains speculative, e.g. the role of subclinical **pain** in problems of **aggression** in **companion animals**. Many infections are subclinical in the early stages and towards the end of full recovery, and this may be a time when there is a high risk of spread; similarly, some carriers post-infection continue to shed the pathogen but show no clinical signs and are otherwise healthy. For this reason quarantine facilities may be imposed when the **health** status of a new individual to an area remains unknown. Quarantine involves **isolation** of the individual for a predetermined period and can be a significant **stressor**, as individuals are often subjected to restricted **space**, close **confinement** and may be deprived of their normal social contacts and interactions for a prolonged period (**see: Social stress**) in the interests of health control. Environmental **enrichment** can be particularly important to these animals.

Vaccination may be used as an alternative precaution to quarantine but, in some cases, it can be difficult to distinguish between antibodies mounted to the vaccination and those relating to a subclinical infection (which might interfere with the efficacy of the vaccine). Therefore, blood tests pre- and post-vaccination may be required, not only to establish the efficacy of the vaccination procedure but also to ensure that a subclinical infection is not present.

(DSM)

Subjective experience

Subjective experience is sometimes used as another term for conscious mental states of humans or animals (**see: Consciousness**). These states are taken to be subjective in the sense that they exist only by virtue of being the object of some kind of awareness. Whereas it makes sense to say that I have a wound on my arm but that I am not aware of it, it does not in normal circumstances seem to make sense to say that I have a certain feeling, such as a feeling of **pain**, but am not aware of it.

The objective-subjective distinction is sometimes taken to relate primarily to a difference between the way things *appear* (e.g. there is an oasis ahead) and the way things *are* (it is a mirage). Things can appear differently to different observers, depending on, among other things, ambient conditions (e.g. light levels), the perceptual apparatus of the observer (some animals see in black and white) and salience (parent birds attend to the chick's gape). The term 'subjective experience' is often used to mark this fact. From one view, science is an attempt to understand the world as it really is, free of subjectivity. The scientist moves beyond subjective experience and examines objective reality.

(PS)

See also: Feelings

Submissiveness

Submissiveness describes the behavioural **signals** and actions made by an individual that demonstrate its subordination to another individual(s) within its **social group** (**see also: Dominance; Hierarchy**). Such behaviours serve to appease more dominant individuals, prevent escalation of **aggression** and promote the successful integration of the individual into the **group**. Some individuals prefer the term 'appeasement gesture', as this emphasizes their proximate function, rather than the potentially less reliable predictive value of general social status. Submissive signals aim to dissipate aggressive threats by showing a lack of threat on the part of the submissive individual, and include avoiding eye contact, lowering of the ears and/or tail, grinning, crouching or even rolling over to expose the abdomen. Such signals are often the opposite (antithesis) of the signals displayed by the dominant individual.

(KT)

See also: Appeasement

Subspecies

A subspecies is a taxonomic rank, subordinate to species. In accordance with the International Code of Zoological Nomenclature, a subspecies is identified by the Latin binomial of the species followed by the name of the subspecies (resulting

P.586

in a Latin trinomial). For example, tigers are known by their Latin name *Panthera tigris* (the Latin binomial); the Sumatran and Bengal subspecies follow the nomenclature: *Panthera tigris sumatrae* and *P. t. tigris*, respectively. Subspecies are characterized by differences in morphology or through different DNA sequences. The distinction between a species and subspecies tends to revolve around why the groups do not interbreed. If two groups do not interbreed because of intrinsic genetic differences, they tend to be classified as separate species. If they do not interbreed due to some geographical barrier, but would freely interbreed should the barrier be removed, then they are classified as subspecies.

(PE)

Suffering

Suffering refers to the presence of highly unpleasant or **aversive** mental states in animals. A paradigmatic case of suffering is **pain**, which has been defined by the International Association for the Study of Pain (IASP) Task Force on Taxonomy as ‘an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage’ (IASP, 1994). However, it is important not to assume that all suffering involves pain. First, the word ‘suffering’ indicates simply that the states in question are unpleasant, or aversive, to a degree where it becomes a problem. Pain, on the other hand, can come in degrees, ranging from very mild to very strong; and there is no reason to claim that mild and controllable pain amounts to suffering - although, clearly, people will disagree about where to draw the line on what is acceptable. Secondly, there seem to be forms of suffering, not involving tissue damage, that typically feel very different from pain. Examples include **fear**, **anxiety** and nausea.

There is ongoing discussion, particularly in connection with fish, about whether certain animals can be said to suffer in the full sense of the word, or whether they merely have the ability to react to physical and other stimuli without actually feeling pain and enduring other forms of suffering (**see: Fish welfare**). Those who contend that fish and similar animals cannot feel pain or suffer in other ways point out that these animals lack the neural structures involved in human pain and suffering. Those maintaining that a wide range of animals, including fish, are able to suffer argue, first, that other neural structures in these animals may do the job; and, secondly, that behavioural data seem to support the hypothesis that these animals are able to feel pain and suffer. Given the scientific uncertainty, some people conclude that it is best to give animals the benefit of doubt and assume that they are able to suffer (**see: Precautionary principle**).

IASP (1994) Part III: Pain terms: A current list with definitions and notes on usage. In: Merskey, H. and Bogduk, N. (eds) *Classification of Chronic Pain*, 2nd edn. IASP Press, Seattle, Washington, pp. 209-214.

Suffering - its recognition and assessment

René Descartes, in his writings, considered that animals could *feel* **pain** but the question for him was whether they could actually *suffer* pain. From his viewpoint, animals were analogous to machines and, unlike humans, lacked **consciousness**, as they could not reason, reflect or even speak and, because animals lacked those abilities, they could not suffer. **Jeremy Bentham** questioned this view: ‘The question is not, can they reason? Nor can they talk? But, can they suffer?’

This controversy over whether animals can suffer still exists today, not so much in relation to mammals, where it is generally accepted that they can suffer, but more when considering other chordata (phyla such as birds, **reptiles**, amphibians and fish) (see EFSA, 2009). Some think that only humans can truly suffer, whereas others are of the view that all those with a nervous system are able to suffer, but to varying degrees according to the development of their nervous systems. In addition to vertebrates, this includes some invertebrates such as cephalopods (e.g. octopus) and some crustaceans (e.g.

lobsters), which do not have a **central nervous system** as such, but have a series of ganglia that may assume the same function.

Suffering is intimately linked with consciousness, **self-consciousness**, **awareness** and **self-awareness**, but it is always associated with unpleasant mental experiences that encompass different **feelings**, such as pain and **distress**. These mental states are brought about by responses to stimuli that may be external (e.g. injury, cold, barren or small cages) or internal (hunger, thirst, social isolation). It seems likely that animals that are aware of themselves in relation to others may potentially suffer more than those that are just sentient, i.e. have the ability to experience and respond to 'pain and pleasure' (see: **Sentience**).

Suffering is used as a generic word to cover those adverse mental states and would include, in addition to those above, feelings such as **fear**, **frustration**, **boredom**, grief and discomfort. Suffering is used in an holistic (all-embracing) sense to denote the breadth of mental experiences an animal might be feeling. For example, an animal that has a broken leg is likely to be in pain (suffering in the present), but may also associate that pain with someone who caused it (suffering due to fear in the presence of that person, or **anxiety** when anticipating their presence). Furthermore, that animal may be unable to **play**, or seek shelter, or find food and water, and so it will experience other feelings such as distress, discomfort, **hunger**, thirst (see: **Drinking behaviour**) and frustration. It may also think that it will soon be hungry and that it will be unable to forage or kill for food, or escape in the presence of a predator (thoughts about suffering in the future). It is not clear to what degree mammals other than the higher primates are able to reflect in this way (so-called '**mentation**'; see DeGrazia, 1996).

As knowledge increases about the sentience of animals, the difference between non-human animals and humans seems less clear-cut, as observed by **Charles Darwin** (1871) in *The Descent of Man* over 100 years ago: 'There is no fundamental difference between man and the higher animals in their mental faculties'. The **Brambell Report** (1965) noted that farm animals were sentient, i.e. 'Animals show signs of suffering from pain, exhaustion, fright, frustration and can experience emotions ... and pleasure' and considered 'that it is morally incumbent upon us to give the animal the benefit of doubt and to protect it so far as is possible from conditions that may be reasonably supposed to cause it suffering, though this cannot be proved'.

P.587

The study of animal suffering is important as it underpins public policy on how we ought to treat animals (see: **Ethics**) and provides evidence for the suitability, or otherwise, of the methods we use to farm, keep and care for animals (FAWC, 2009). In any system of husbandry some suffering may be necessary and justifiable, but to cause more than the minimum level is unacceptable and so there is a notion of 'avoidable suffering'. For example, farm animals are subjected to uncomfortable procedures such as mixing with other animals that come from different farms at markets, or the discomfort of vaccination to prevent disease, testing for **diseases** such as tuberculosis, and **transport**: all these will cause some degree of suffering but are seen as necessary and unavoidable for farming. However, there are also approved surgical mutilations such as **docking** and **castration** that are carried out with no **anaesthesia** nor long-term **analgesia**, and the suffering caused therein could have been avoided had these measures been taken.

Recognition and assessment of suffering

Not all animals will suffer negative emotional states to the same extent or in the same way as others. It will vary according to: (i) the adverse physical, physiological and psychological circumstances in which an animal finds itself; and (ii) the cognitive capacity of the species, as well as the individual being and its past experiences in life. Furthermore, *recognition* of suffering will depend on the anatomical and physiological characteristics of the species or the individual being studied. In addition, the environmental circumstances in which the observations are being made will play an important part; for example, one is more likely to be able to observe a greater variety of behaviours in complex rather than in simple environments.

While it is difficult, it is not impossible to assess the level of suffering. Research into animal **welfare** is an evolving science, and many new ideas of **welfare measurement** are being developed. They include observing an animal's behaviour, measuring physiological changes, monitoring **brain** function and associated neuropeptide levels and their receptors, and even trying to devise experiments that ask an animal what 'it thinks' about a particular **resource** or environment (see below). At a basic level, an assessment of **mortality**, **morbidity** (**health** records) and measuring of productivity in some way (e.g. in farmed animals **growth rate**, milk production, fertility, fecundity) of animals kept under certain **housing** and husbandry conditions are all valuable, but not complete, measures. All such observations have to be compared with the levels (prevalence, i.e. the rate at which a factor is observed at any one point in time) or frequency of occurrence

(incidence, i.e. the rate at which the factor occurs in unit time) of the same measures in other animals considered to be 'normal' in those circumstances. It is perhaps worth emphasizing that it is not to do with what is 'natural' that relates more to its wild state.

The assessment of the degree of suffering can then be determined by how far those measures have deviated from normality and, in general, the greater the deviation, the greater is the suffering. Suffering, or severity as it is sometimes referred to, is a combination of intensity and duration: the greater the deviation and the greater the time it lasts, the greater will be the severity. Obviously, this is only true when the behavioural or clinical **sign** reflects an adverse effect, such as loss of body weight, **lameness**, increases or decreases in body temperature, and so on. But it is also applied to other measures such as blood **corticosteroid** levels and autonomic responses such as **heart rate** and **blood pressure**. In these latter cases it is important that these are seen in context, as many of these measures are often elevated in circumstances relating to good as well as to poor welfare, e.g. **play**, exercise. Furthermore, even inquisitiveness, which is associated with a mild form of **arousal**, will show several identical types of change, although they may be quantitatively different, e.g. heart rate, rise in blood pressure, increased alertness. In addition, there may well be other caveats and concerns in interpreting these signs; for example, playing with companions for longer than normal is unlikely to be a cause for concern, but excessive weight gain through overfeeding/-eating is a predictable indicator for future suffering (arthritis), even though an animal might enjoy eating (see: **Positive welfare**).

Behavioural measures

When assessing an animal for **signs** of suffering it is important to minimize any interaction between the observer and the animal. Undisturbed or unprovoked 'natural' behaviour can reveal much about how an animal is feeling. Play would indicate happiness, **lying** and sleeping or chewing the cud could reveal a lack of fear and contentment, whereas an animal that is lying on its side, kicking at its abdomen and groaning would indicate pain, especially in the context of it just having been docked or castrated or had some other painful operation, or was suffering from colic. Excessive self-licking or stereotypic behaviour (see: **Stereotypies**), such as barchewing or licking water bottles, could indicate boredom. Frustration again may be indicated by animals trying to carry out natural behaviours but doing them in a modified form and for longer periods of time. For example, **rabbits** in small, barren cages repeatedly scratch the floor of the cage in an attempt to burrow; they try to rear up to scan the environment for danger, but they are unable to do so because the height of the cage will not permit it, so they end up doing a half-rear and then sit down again.

Immobility may indicate **apathy** and boredom or an animal being in pain as it hurts to move. By comparing the times spent carrying out these **abnormal** behaviours, or normal behaviours carried out more frequently or for longer, one can make a judgement on the individual and whether it falls within a 'normal' range. Moreover, it is possible to compare two different systems of husbandry looking at the prevalence of normal and abnormal behaviours, e.g. stereotypic behaviour. One can also measure the behavioural diversity of an animal or **group** of animals. For **companion animals**, where owners get to know their animals extremely well, a **dog** not getting out of bed to greet you in the morning, not barking when the doorbell sounds or not wanting to come out for a walk, or a **cat** not asking for food, are all signs that indicate a change from normal for that individual animal, and have to be explained in some way.

It is also possible to use behavioural measures to deliberately provoke an animal to respond and observe if it responds in a normal way. For example, by changing the environment one can assess inquisitiveness and other sorts of response times. In

P.588

rats, turning the lighting colour from white to red to mimic night-time (rats cannot see red and so it appears dark to them) should stimulate their night-time behaviour (when they are usually most active) within a few minutes (see: **Light and behaviour**). If they do not do this then something is wrong.

Pressing on a site on the body is often used to make a veterinary diagnosis, e.g. to determine if there is a fracture or deep wound, as it will cause an animal to react. The exact response will depend on the species and the temperament of the individual animal, and it may react by trying to bite, by vocalizing or by making vigorous escape attempts. Again, a failure to respond would normally mean that the animal is not in pain but, if it does respond, then that is an important sign.

Asking the animal

The ultimate expression of how an animal feels about its environment is how it behaves, i.e. behavioural measures are arguably the most relevant measures of good and poor animal welfare. Giving animals a choice of environments (putatively good or bad), making them work for a resource (see: **Economics of behaviour**) and measuring their **cognitive bias** (i.e. are they feeling optimistic or pessimistic) provide additional tools for discriminating whether an animal feels it is in a good or

poor environment, or prefers one thing to another. By observing what environment animals choose to be in when given a choice, and how hard they will work to gain a resource of some sort, or how hard they will work to stay or leave a particular environment, can be interpreted as reflecting a preference. How closely that is correlated with long-term welfare is debatable (animals might choose to 'overeat'), or whether it is an ideal environment as opposed to the best on offer.

Other signs

Animals that do not eat lose body weight, and so measurement of body weight can be a helpful guide. An animal that has lost 20% of its body weight is likely to be suffering more than one that has lost just 5% over the same period. Animals with abnormal **postures** (hunched, holding a limb off the ground, as in lameness) or appearance (starey coat, ruffled feathers - both indicating a lack of **grooming**) may also be suffering. In farmed animals a decreased productivity such as a reduction in growth rate or milk yield may indicate a problem.

Another important point to note is that all clinical signs, and physiological and behavioural measures, can usually be scored objectively, i.e. in a repeatable and reliable manner, and it is the interpretation of those signs where the subjective element of welfare assessment comes in (validation of what an increase in a particular behaviour or blood hormone actually means in terms of **well-being**). Any clinical signs of disease, e.g. spasms, fits, breathing difficulties, discharges, etc. all indicate a change from normal, and so have to be examined carefully.

Interpretation of 'abnormalities'

Several criteria are important: one is whether the sign can be recorded accurately by different observers and, secondly, how one interprets those abnormalities in terms of suffering. Inter- and intra-observer variation can be minimized through training and ensuring that the sign to be scored or evaluated is simple. Whether it is present or absent would be the best evaluation, but to ask whether an animal is in pain presupposes an assessment of multiple signs, and is bound to cause more difficulties and more variation. Secondly, it may be possible to record a sign on a numerical basis, e.g. body weight loss, body temperature, cortisol levels, heart rate.

Alternatively, quantifying lameness, diarrhoea or breathing difficulties is far more difficult, but can still be objectively recorded as with numerical data. This may be by banding - e.g. for lameness it can be from normal to just limping to marked lameness to hopping lame, being unable to weight bear at all. This can give us 3 or 4 bands with which to categorize animals. Having made objective observations of both quantitative (metric) and semi-quantitative (bands or parametric) signs, they then have to be interpreted in terms of animal well-being, and this is where the subjective step comes in. It is not the observation of the signs that is subjective (given the narrow choice of a sign being only present or absent), it is how that sign is 'subjectively' interpreted in terms of animal suffering that is key (i.e. does the sign really reflect suffering?). In another sense, deviation from normality, whether it is because of pain, distress, frustration, boredom or whatever, does not matter, except from the point of view of making a diagnosis on the cause, as it may be possible to treat by avoiding or alleviating an animal's condition in some way, e.g. through the use of analgesics.

Supplementation

Supplementary feeds are usually based on processed feeds, or concentrates, and are most likely to consist of cereals or other high-energy and protein feeds (**see: Concentrate feeding**). They are usually made into a pellet, or compound, with the addition of a binding agent. They are brought on to the animal unit either in bags or they may be delivered by an auger into a feed bin. The cost of these processes makes compound pellets an expensive form of food, unless the raw ingredients are inexpensive. In deciding how much supplementary feed to offer animals, an animal manager will normally estimate the anticipated increase in productivity and determine a breakeven point where additional feed would provide no additional financial return.

However, feeding additional concentrates will often do more than simply increase **growth rate** or milk yield, and consideration should be given to changes in product composition and savings in forage when concentrate intake is increased. For example, with dairy cows, the provision of additional supplementary concentrated feed will reduce milk fat content and, to a lesser extent, protein content will increase, as

P.589

the amount of concentrate and the ratio of glucogenic to lipogenic precursors increases. At most levels of concentrate intake, milk fat and protein yields increase with concentrate intake but, at very high intakes, in excess of approximately 12 kg/day, the milk fat content declines rapidly with additional concentrate, so that milk fat yield declines (the low milk fat syndrome). Under virtually all circumstances this will be an uneconomical level of supplementary concentrate to feed to cows.

The saving in forage when concentrate supplements are fed should enable the stocking rate to be increased. The manager will decide how to maximize income, and this will entail looking at responses to the different resources available, in particular the most limiting ones. Feeding additional concentrates may increase the gross margin per hectare on a dairy farm (largely because **stocking density** increases) but reduce the gross margin per litre of milk (because feed cost per litre increases). Under strict quota limitations, therefore, farmers may prefer to feed low levels of concentrates but, if the land area of a farm is restricted, the farmer may prefer to feed more. The output per animal is likely to be particularly important to farmers keeping pedigree stock, who may feed high supplementary concentrate levels so that the animals' performance is high and others are encouraged to buy them.

The allocation of supplementary concentrates should take account of the animals' physiological state - lactating or nonlactating, pregnant or non-pregnant. As nutrient intake increases, particularly energy, productivity may increase up to a certain level and then no further increase can be obtained from greater energy intakes. The extra energy may be stored as body tissue, to be used at a later date, but other nutrient excesses may be excreted or become toxic. The response of high-yielding cows to increased energy supply from concentrates may be offset by a similar reduction in low-yielding cows, if they receive fewer concentrates.

However, it may be worthwhile allocating different forms of supplementation to differentially productive animals, e.g. rumen-protected protein and mineral/vitamin supplements may be reserved for high-producing animals. Mineral supplements should be provided in accordance with local deficiencies in forage and/or soil. For example, phosphorus deficiency is prevalent in much of northern Australia because of weathered soils and low-quality forage.

(CJCP)

Sympathetic nervous system

The sympathetic nervous system (SNS) arises from the thoracic and lumbar spinal cord (spinal segments T1-L3) and is regulated through the **hypothalamus**. Myelinated preganglionic sympathetic nerve fibres give rise to unmyelinated postganglionic nerves that are generously dispersed throughout the body. Most organs in the body, as well as somatic structures such as the skin, muscles, mucous membranes and certain bones, are innervated by this subdivision of the **autonomic nervous system**.

Activation of the SNS results in what may be described as a general excitation of effectors, triggered primarily by the release of **catecholamines**, such as **norepinephrine** from postganglionic sympathetic **neuron(e)s**, and **epinephrine** from the **adrenal gland** medulla. The terminal branches of SNS postganglionic fibres end in varicosities that synapse with

effectors. Norepinephrine is produced and stored within these varicosities, and can later be released into the synaptic cleft as and when required. The SNS is characterized by a very high ratio of post- to preganglionic synapses (termed divergence), which enables it to excite many effectors simultaneously. These effects are magnified in effectors that also boast adrenergic receptors through the generalized release of epinephrine into the bloodstream.

The SNS controls those activities associated with the mobilization of energy necessary for an organism to respond to a challenge, such as a **stressor**. Responses governed by the SNS include modulations in cardio-pulmonary, respiratory and pupillary activity, besides the mobilization of fat and glycogen from liver hepatocytes and adipose cells. The activation of the SNS, for example, increases **heart rate** and respiration rate, redirects blood from skin and splanchnic vessels to voluntary muscles, regulates the secretion of hormones (e.g. epinephrine), increases blood glucose levels and causes piloerection in preparation for a fight-or-flight reaction. Aside from times of **stress**, in healthy animals the SNS is always tonically active, meaning there is a continuous low level of discharge of nerves facilitating their effectors.

Symptom

Symptoms are what a patient reports to the doctor that normally cannot be seen, e.g. feeling nervous, having a headache. Clinical signs are those that the doctor can observe for her/himself. It follows, therefore, that animals can only be assessed by the use of clinical signs and not symptoms.

(DBM)

Synchronization of behaviour

Synchronization of behaviour literally refers to acts that occur together, although the term may also be used to refer to behaviours that are related in time in some other way. While all synchronized behaviours share this common temporal characteristic, there are diverse reasons why and how certain behaviours may become synchronized. Synchronization may occur between animals with similar objectives, e.g. synchronization of **mating behaviour**, or opposing objectives, e.g. **hunting** versus hiding in predator and prey.

Some factors resulting in synchronization relate to the physical environment and others to the social environment, or to a combination of these. **Proximate factors** resulting in synchronization include the appearance of a resource that stimulates the behaviour, e.g. the arrival at a water hole by migrating animals that results in synchronized **drinking behaviour**. In the latter example the synchronization is incidental, while in other situations it may be intentional - for example, the synchronization of **feeding** and vigilance behaviour within a **social group** in the presence of a potential threat. The behaviour of another may be important in triggering synchronization, e.g. behaviours affected by **social facilitation** or behaviours that are being mimicked. In some cases, specific physiological factors are important in helping to maximize the fitness benefit of synchronization, e.g. the hormonal effects on breeding and migratory behaviour in relation to lunar or diurnal factors.

P.590

In **captivity**, behaviours that are normally synchronized may be prevented, and this may give rise to **welfare** concerns, through the deprivation and/or **frustration** of adequate amounts of motivated behaviour. For example, the provision of inadequate **space** may prevent synchronous feeding, drinking or **resting behaviour**, and physical barriers between members of the opposite sex may prevent mating. The importance of behavioural synchronization in the design of animal facilities should therefore be considered (**see also:** Confinement).

Systemic measures

Systemic measures are those taken from the animal that are a result of the additive and subtractive contributions of the entire variable being measured. For instance, systemic **blood pressure** is the result of the pressure in all the vessels of the body, from the aorta to the vena cava. Similarly, the concentration of a hormone measured in the circulating blood is a result of all of the hormone being cleared and produced in the entire body at the time at which it is measured.

(DCL)

T

Tail-biting

Tail-biting is an abnormal injurious behaviour that occurs predominantly, but not exclusively, in intensively housed pigs. In essence, a **pig** will take the tail of a pen-mate in its mouth and chew or bite on it. Initially this may appear to cause little or no damage to the tail and is tolerated by the other pig; however, the biting may intensify over time until the tail bleeds and becomes painful. It is unlikely that all outbreaks follow this pattern; however, at some point a tail is damaged somehow and this presence of blood results in a sudden escalation of the behaviour and thus of damage. Without intervention the biting can become generalized and lead to dramatic damage and eventually **cannibalism**. Even small amounts of tail damage can have a major impact on the health of the bitten pig, causing abscesses in the hindquarters, lungs, spine and pelvic region, as well as an increase in the spread of **diseases**.

Tail-biting is described as a multifactorial problem involving both internal and external risk factors. These include genetics, **health**, high **stocking density**, poor nutrition, insufficient temperature control and a lack of rooting material. Experiments attempting to induce outbreaks by modifying one factor alone have often failed, suggesting that outbreaks occur only when enough factors combine to make the pigs sufficiently uncomfortable. This association between stressful factors and biting implies that it may be indicative of reduced **welfare** of both the biter and the bitten individuals.

Estimating the extent of the tail-biting problem is difficult as the levels vary according to the production system, whether tails are docked and how the estimate is produced. Records from abattoirs place the level at around 3% in the EU (EFSA, 2007); however, the same report stated that abattoir data may record fewer than half the lesions found on farms. A survey of farms in the UK found that 66% had experienced tail-biting in the previous year (Chambers *et al.*, 1995), and thus it is a considerable problem. It is rarely seen in extensive production systems, even when docking is not used.

Tail-docking (**see: Docking - tail**), where either the tip or most of the tail is clipped off shortly after birth, has been the most common technique used by farmers to prevent tail-biting. There are several welfare and ethical concerns regarding this procedure and, although it is thought to reduce the incidence of tail-biting, it does not eliminate the problem. The search for viable alternatives such as provision of rooting materials is continuing.

Tail tip necrosis

Tail tip necrosis can affect many species, but is commonly used to describe a condition in cattle that begins by the tail being stepped on, causing a lesion to form. It is more prevalently found in cattle kept on slatted floors, at high stocking densities, in warmer weather and in cattle above 200 kg in weight. The lesion at the tail tip starts off swollen, followed by **inflammation** and suppuration. In severe cases of infection, metastasis to other parts of the body can occur and result in abscesses and osteomyelitis. Treatment includes antimicrobial therapy, tail amputation (**see: Docking - tail**) and, in worst cases, **slaughter** of the animal.

(LMD)

Tamarin

Together with the Goeldi's **monkey** and the **marmosets**, tamarins belong to the family Callitrichidae, subfamily Callitrichinae and are distributed throughout the Atlantic and Amazonian rainforests of South America. There are four species of lion tamarins (*Leontopithecus*) and 15 species of tamarins (*Saguinus*; Rylands *et al.*, 2000), of which *Saguinus fuscicollis*, *Saguinus labiatus*, *Saguinus mystax* and *Saguinus oedipus* are the most frequently used in laboratory experimentation. *S. oedipus*, despite being endangered, was used to study colonic adenocarcinoma, as it is the only primate model that, like humans, spontaneously develops colitis and/or colonic cancer. Several species of callitrichines are either endangered or critically endangered, and **reintroduction** programmes are under way for some.

Tamarins are similar to marmosets in many respects. They are **diurnal**, arboreal, give birth to twins as the norm and all group members assist with infant care. Olfactory **communication** is highly developed. Tamarins can live up to 15-20 years. *Saguinus* become sexually mature at 18 months, *Leontopithecus* at 24 months.

However, tamarins are different from marmosets in some critical ways that impact on their **welfare** and captive conditions. They are slightly larger (average adult body weight for both males and females is 400-500 g for *Saguinus* and up to 700 g for *Leontopithecus*), have larger **home ranges** (up to

P.592

50-100 ha) and longer daily path lengths, related to a more frugivorous diet and less dependence on gum-feeding.

Tamarins are **insectivore**-frugivores and their dentition is not adapted for gnawing. The long, slender hands and fingers of *Leontopithecus* are used for probing for concealed prey in specific microhabitats. A considerable proportion of prey items are located by touch rather than by sight, and the most important foraging site is epiphytic bromeliads. There are also differences in foraging strategies among *Saguinus*. Three distinct insect-foraging patterns have been described. The first pattern is shown by *Saguinus geoffroyi*, which hunts for insects on thin, flexible branches in the low shrub layer of the forest understorey. The second is shown by *S. labiatus*, *S. mystax*, *Saguinus imperator* and possibly *Saguinus midas*, which have a similar insect-foraging style to the marmosets, exploiting insects on leaves and branches in the lower and middle levels of the forest.

Visual scanning plays an important role in the detection of their prey. The third pattern is shown by *S. fuscicollis* and possibly *Saguinus nigricollis* and *Saguinus bicolor*. These species are predominantly manipulative specific-site foragers, concentrating their feeding efforts on relatively large cryptic prey. In those species of tamarin studied in the wild, ripe fruits account for 20-65% of total feeding time; nectar is also consumed, principally in the dry season. Like marmosets, without natural light tamarins need a vitamin D₃ supplement added to their diet of fruits, vegetables and animal protein. Feeding enrichment should take their natural feeding adaptations into account (e.g. hiding food in bromeliads for *Leontopithecus*).

Like marmosets, tamarins are arboreal but have an even greater tendency to avoid the ground, where they behave nervously. It is therefore important to provide appropriate cage furnishing to increase spatial complexity and allow better utilization of the vertical, that is, the arboreal dimension. The type of cage furnishing, its dimension, orientation and its placement have to vary to take into consideration specific adaptations, needs and **preferences**.

Generally, breeding of *Saguinus* is less successful in **captivity** than for *Callithrix*, and prior experience with offspring is even more critical for parenthood. Infants are provisioned and carried for longer periods. In general, tamarins are even more aggressive towards unfamiliar **conspecifics** than are marmosets, and visual barriers must be present to stop threats and inter-group aggressive behaviour that may lead to redirected **aggression** towards **group** mates. It is argued that, because of these differences in weight, home range size, daily path length, **reproduction** and arboreality between marmosets and

tamarins, in the laboratory, minimum cage sizes should be larger for tamarins than for marmosets (Prescott and Buchanan-Smith, 2004).

All tamarins have claw-like nails to facilitate grip, and all cage furnishings should take grip into account. **Locomotion** is primarily quadrupedal, but vertical clinging and leaping are seen in several species. Positioning of vertical supports is particularly important for *S. fuscicollis*, which locomotes extensively by vertical clinging and leaping. *Saguinus* usually sleep in vine tangles and forks of trees, and in captivity secure nesting places such as a nestbox some distance from the **floor** should be provided. *Leontopithecus* are unusual in that they primarily use holes in tree trunks and branches as sleeping sites, and therefore providing tree holes in captivity is appropriate.

Some tamarins form stable mixed-species associations in the wild. Those between *S. fuscicollis* and either *S. labiatus*, *S. mystax* or *S. imperator* are the most stable. Mixed-species groups of *Saguinus* have proved a successful method of housing, which has a number of advantages such as greater activity and increased social encounters. However, careful monitoring is necessary around the time of the birth of offspring, as individuals may get protective of young. Other important considerations are to provide food and water in multiple locations, as *S. fuscicollis* is dominated by its associating species. Multiple nestboxes should also be provided.

All callitrichines possess specialized scenting organs and have a rich repertoire of chemosignalling behaviours. The most conspicuous of these are scent-marking patterns, involving the circumgenital and subpubic glands. Scent-marking itself and the chemical **signals** deposited are important in many areas of their behavioural biology, such as reproduction, and possibly territorial defence and inter-group spacing. Tamarins also have a wide range of **vocalizations** and a variety of other species-specific **postures** and facial expressions that can be used to monitor behaviour and welfare.

Marmosets and tamarins generally do not like being handled. However, they can be trained using positive reinforcement techniques (**see: Reinforcement**) to cooperate with routine husbandry procedures such as capture, weighing, veterinary procedures such as oral administration or palpation, or to provide samples (such as saliva or urine). Marmosets and tamarins are increasingly producing triplets in captivity, probably due to their rich diet. **Hand-rearing** of the third infant, or of rejected infants, is feasible but the infants must be reintroduced into a conspecific group as soon as possible to minimize the serious adverse effects of separation from their natal groups.

Tameness

A standard dictionary definition of 'to become tame' would be to become gentle, tractable or docile, and 'to tame' a **wild animal** would be to bring it from the wild state into submission and under human control. But this does not

P.593

explain what it means to be wild or tame. A wild animal is usually thought of as one that is fearful of humans and runs away if it can. However, this **fear** of humans is in itself a behavioural pattern that has been learned from experience of human **predation** over countless generations. A species of animal that has had no contact with humans as predators over its evolutionary history has no fear of them and can be quickly exterminated, like the dodo, or like the fox on the South American island of Chiloe, which was killed by **Charles Darwin** in 1834 and described by him thus in his description of the voyage of the HMS *Beagle*:

A fox (*Canis fulvipes*) of a kind said to be peculiar to the island, and very rare in it, and which is a new species, was sitting on the rocks. He was so intently absorbed in watching the work of the officers, that I was able, by quietly walking up behind, to knock him on the head with my geological hammer. This fox, more curious or more scientific, but less wise than the generality of his brethren, is now mounted in the museum of the Zoological Society.

In order to tame an animal that has a perception of humans as predators, either potential or real, its fear of danger must be annulled. This can be most easily achieved with very young animals that can be persuaded that the tamer is a substitute parent. This can be done either by feeding the baby or by changing its **imprinting** from the mother to the tamer, as was described by **Konrad Lorenz** in his well-known and memorable account of the goslings that followed him everywhere. A crucial part of taming is **habituation**, the process in which new and unusual stimuli are slowly and continuously presented to a wild animal, so that it becomes accustomed to the presence of a person, or another animal, or a vehicle, and over time loses its fear and its flight response.

Lack of fear may be seen as the essence of tameness, but the extent of this fearlessness depends on the integration of the many facets that make up the complex characteristics of the species. An animal will be more or less fearful and therefore more or less easy to tame depending on whether it belongs to a social or solitary species, whether it is normally a predator or prey and, if it is a prey, whether it escapes by fleeing or hiding. A burrowing species like a **rabbit** can be easily tamed, while a superficially similar species like a hare that depends on speed for escape cannot be tamed. Similarly, a wild **goat** that is by nature a mountain animal and depends on agility for escape has less instinctive fear than a gazelle, which is a plains animal depending on speed for escape from predators. This means that the natural flight distance of a goat is much shorter than that of a gazelle, and partly explains why goats could be easily tamed and then domesticated by prehistoric people, while gazelle remained wild (**see also: Domestication**).

There is one form of taming in which loss of fear is not paramount, this being in the physical and mental subjugation of individual animals for their use by humans: the **horse**, the **elephant** and **camelids** have traditionally been 'broken in', often by cruel methods rather than by the gentler method of habituation. However, it has been shown that horses can become accustomed to a harness and rider more quickly and with less trauma than by physical subjugation through a process referred to as '**horse whispering**'.

The state of wildness or tameness of a species of animal is closely connected to the culture of both the human and the animal populations. **Culture** can be defined and seen as a way of life imposed over successive generations on a society of humans or animals by its elders. Where the society includes both humans and animals then the humans act as the elders.

The process of taming a wild animal, whether it is a wolf or a wild goat, can be seen as changing its culture. The animal is removed from the environment in which it learns from birth either to hunt or to flee on sight from any potential predator, and it is brought into a protected place where it has to learn a whole new set of social relationships as well as new feeding and reproductive strategies.

It is common knowledge that in any region of the English countryside, where there is a culture of **hunting** foxes with hounds or shooting them as vermin, the foxes will be wild and fearful and will be rarely seen, but in towns where they can scavenge or are even fed by householders, foxes have little fear and are even known to come into people's houses. These animals have not been actively tamed but they have lost their fear of humans and developed a culture in which they exploit, albeit unconsciously, the urban dwellers' desire for contact with the natural world.

Other common species in which there is a dichotomy between the wild and the tame are the rabbit, the brown **rat** and the house **mouse**, which are all treated as vermin in the wild but, as tamed, domestic animals, they become muchloved animal companions (**see: Companion animal**).

Without hunting, animal populations will become increasingly tame, as can be seen in the wildlife parks of East Africa where herds of large **ungulates** and even the large **carnivores** are seemingly unaffected by the presence of crowds of people in vehicles all round them. It will be one of the great problems of the future how to manage the wild places and their faunas, because it will not matter whether these faunas include African elephants, Asian lions or giant tortoises - they will become increasingly hedged in and the wild will merge with the tame.

Taming

Taming refers to the process whereby an animal is made more approachable and tractable to humans. As such, it may be an important element of the **socialization** process for animals living within human society, but the two are not synonymous. Socialization is a broader process, in which an animal learns appropriate behaviour towards all members of its **social group**. A tame animal may still show inappropriate behaviour to other species, e.g. a **dog** may be tame but not well socialized towards **cats**, and it may merely tolerate humans (not flee when approached) without being socialized towards them (positively engage in a social context).

Taming may be established by a combination of gradual **habituation** (**see: Desensitization - systematic**) and positive reinforcement (**see: Reinforcement - types of**) and is a lifetime trait, although the ease with which an animal may become tame has a genetic element. Taming should not be

P.594

confused with **domestication**, which arises as a result of interaction with people (taming) and **selection** over generations.

(DSM)

Taste

Chemoreception by taste (gustation) has been extensively studied in both man and animals. Generally, four primary tastes are identifiable and can be correlated to physiological requirements: sweet for nutrient supply, salt to control electrolyte balance, bitter to avoid toxins and sour to regulate the body's pH. Bitter compounds, such as tannins, also reduce the digestibility of plants, providing another reason for herbivores to avoid them. There may also be separate metallic and monosodium glutamate tastes, but probably all tastes derive from combinations of **signals** from these four primary taste receptors. The receptors are located in specific areas of the tongue, and differ in their taste discrimination, sensitivity and positioning on the tongue between species. For example, in man the tip of the tongue is sensitive to sweet and salt taste, but in cattle sweet taste is mainly at the base and salt at the tip. This may derive from the longer period of time that food is masticated in the middle to rear section of the buccal cavity in cattle compared with man.

Different animals derive different sensations from food items, in relation to the benefit that they derive from them (**see: Euphagia; Hedyphagia**). For example, several compounds that taste sweet to man, such as monellin and thaumartin, do not elicit a similar response in cattle. Cattle generally experience a greater sweet taste from monosaccharides than from disaccharides, with the most potent sweeteners being glycine, sodium-saccharin and xylitol. When presented with sodium chloride, xylitol enhances the salt taste, acting as a flavour enhancer. Tastes can also act antagonistically; for example, the taste of the potent sweetener thaumatin can be reduced by salt, a phenomenon known as mixture suppression. Flavours also function to elicit avoidance and many food components, such as shea nut meal, cherko (dried coffee grounds) and cocoa bean meal, are unpalatable to domestic animals because of their bitter flavour.

Both strong salty and bitter tastes have the potential to reduce the rate of intake of foods, whereas a sweet taste is likely to enhance it. However, at low concentrations animals increase their appetite for feeds if they have enhanced salt taste, with differences in concentration of as little as 1 g Na/kg DM (dry matter) being readily perceived by cattle, demonstrating that for important nutrients there is an optimum concentration in food items that they will recognize and select. Animals may self-adapt to a salty taste over time, i.e. any reduction in palatability diminishes. In ruminants, the regurgitated bolus provides a mechanism for chemoreception of ruminal conditions, especially acidity.

Taste perception develops at an early age. For example, it has been demonstrated in the sheep **fetus** in mid-pregnancy, and maternal diet can affect dietary preferences of juveniles through *in utero* influences. Taste perception and discrimination thresholds change with advancing age. In cattle, the discrimination threshold to sucrose is less for calves than for adult cows. In sheep, the intensity of salt flavour ascribed to a standard sodium chloride (NaCl) solution increases fourfold from the fetus to adulthood, whereas that to potassium chloride (KCl) decreases by about 30%. Adult cattle prefer pure water to a 0.09 M NaCl solution but calves do not, suggesting that a similar increase in NaCl perception with age occurs in cattle as in sheep. KCl is a less potent salt flavour than NaCl for cattle. The appetite for sodium is particularly acute in many species (salt wisdom), which may show excessive licking behaviour in an apparent attempt to obtain supplementary sodium.

(CJCP)

Taste aversion

A learned rejection of a **taste** stimulus due to previous pairing of that taste with **aversive** consequences such as sickness. Conditioned taste aversions are **adaptive** because they promote avoidance of harmful or poisonous substances. Protocols to study taste aversion learning generally involve presentation of a bottle containing a novel-flavoured solution (such as a dilute saccharin solution) to a thirsty **laboratory animal**, such as a rat. Upon cessation of drinking, an illness-inducing drug such as lithium chloride is administered via injection. A number of days later, the strength of the learning is assessed by giving the rats the opportunity to consume the illness-paired flavour from a bottle for a specified time. If the rat has learned the flavour-illness association, it will drink less of the solution than will a rat that had received saline during the learning phase instead of the lithium chloride. A two-bottle choice procedure may also be used to assess learning in which intake of the toxin-paired solution is compared with intake of a solution that has not been associated with the toxin (usually water). Taste aversion can occur after just one pairing of the novel solution with the effects of a toxin, and the response may be generalized to other, similar flavours.

Teaser

A teaser is a male animal used to assist in domestic **breeding** contexts for the detection of **oestrus** in females. In a natural situation, reproductive males exhibit species-specific responses towards the female (such as sniffing, nudging and nibbling) as a form of **courtship behaviour** prior to copulation. This courtship functions to determine the receptiveness of the female as well as to prepare physiologically both the male (e.g. erection) and female (e.g. **lordosis**) for copulation.

The use of teasers in **horse** breeding is a product of market demands because using a teaser to detect oestrus protects stallions, which are often extremely valuable, from injuries that may be sustained from courting a mare that is not in oestrus (dioestrus or anoestrus).

It is important that the teaser does not copulate successfully. Thus the teaser may be entire (non-castrated) but restrained and/or too short to mate easily with the females (e.g. use of a small pony with horses) or may be physically altered so that he retains his **libido** but not the ability to inseminate. This may involve vasectomy, radical **circumcision** of the penis itself, deviation of the shaft or **castration** and subsequent treatment with **testosterone**. Depending on factors such as facilities

available and personal preference, teasing may be conducted in several ways. Usually, the teaser is controlled by a handler who will direct it to approach females on an individual basis. Alternatively, groups of females may be allowed access to the teaser, which may be confined to a small yard.

The nature of the teaser's job prevents him from being able to consummate normal copulatory behaviours. Teasers are commonly kept in **isolation** or semi-isolation, brought out for teasing (i.e. only during the spring and summer months), often handled inappropriately (e.g. repeated jerking of the bit in the mouth of a horse) and rarely, if at all, get to mate with the females they are teasing.

In racehorse and performance horse breeding, teasers are conventionally ponies with high libido. They are often considered difficult to handle and, as a consequence, are usually handled roughly. Subsequently, this inappropriate handling contributes to the teaser becoming difficult to handle and the decline in its compliance is self-perpetuating. Collectively, the welfare of such animals is therefore a cause of concern.

(AW-S)

Teat order

Within the first few days of life, the offspring of some mammalian species develop a teat order. That is, each individual limits their suckling to one or maybe two teats or nipples, thus reducing competition and allowing **nursing** of all offspring during suckling bouts. Teat orders are reliably established in piglets but can occasionally be found in other animals, such as kittens. With the **intensification of animal production**, many species can produce a larger number of offspring than they have teats to feed with, and thus cross-fostering needs to be performed to ensure all individuals can nurse during a suckling bout.

(LMD)

Telos

The ancient Greek concept of telos corresponds to the modernday notion of an aim, end or purpose and is the root of the word 'teleological' (meaning having to do with a thing's purpose). To understand the concept of telos properly it is necessary to separate two questions about purposes. In the first we ask: What is the purpose of that (e.g. dorsal fin)? In the second we ask: What is the purpose of doing that, or what is that animal aiming to do by doing that (e.g. scratching the ground)? The first question invites speculation about functions. The second is about agency and points towards goals.

Enquiries about purpose often appear in ancient Greek writings, especially in Aristotle's work. The notion that life, or being human, has a purpose is critical in Aristotle's ethical thought and re-emerges in Christian theology. It lies behind the familiar question 'What is the meaning of life?' Turning from human goals to functional teleology, Darwinism asks what role an adaptation plays in making a species fitter for survival.

The notion of a thing's telos focuses attention on the final, or ultimate, purpose of the thing. For this reason the telos is sometimes described as completion, or perfection. There is a direct connection here with the concept of nature, and with the ethical outlook known as perfectionism. The idea that something is natural (and hence the worry that something is unnatural) is both highly flexible and always in need of clarification. Naturalness is generally thought to be a good thing, presumably because we are, somewhat distantly, prone to take an ancient Greek perspective. Perceived departures from what is natural (bald broilers, genetic technology as a whole) are often condemned as unnatural (**see also: Abnormal**).

Perfectionism in animal **ethics** is the belief that animals are best off when they are able to live in the way they naturally do, expressing normal behaviours. One version of this view states that it is unethical to alter farm animals using modern techniques of genetic modification (though gradually bred change is often thought less worrying). Another, associated with the American philosopher **Bernard Rollin**, suggests that the important issue is to let animals live according to the nature that they actually possess, i.e. their telos. In the latter view, it is not enough to ensure that an animal does not suffer or is not frustrated: it should also be allowed to express its nature.

See also: Welfare

Temperament

Temperament has often been broadly defined as a set of relatively stable and genetically based characters that differentiate individuals of the same species in terms of internal dispositions and reactivity to external stimuli. This definition highlights the supposed stability over time and the innate nature of temperament, which, according to some scientists, differs from **personality** in the fact that personality refers to more dynamic and modifiable traits - that is, traits that may change during the course of an individual's lifetime. As a consequence of this difference between the two terms, temperament is usually referred to describing individual differences in non-human animals and, to some extent, in human children, while personality is more commonly applied to adult humans.

Most recent research on the topic, however, opposes this presumed difference between the two terms. Indeed, personality and temperament seem to be influenced by the same factors (e.g. level of particular hormones in the blood, age and sex), share the same level of genetic inheritance across generations (i.e. between 20 and 40% of the inter-individual variation in temperament and personality seems to be genetically determined) and a similar degree of variation within individuals. Inter-individual differences in temperament may have important effects on an animal's behaviour and response to social and non-social stimuli. As such, temperament should be taken into account when, for example, designing **enrichment** devices for **captive animals** or when analyses are performed at the species level.

Temperament test

The aim of a temperament test is to improve our knowledge of an animal and its likely future behaviour above that of chance alone. Temperament tests have been created by a range of organizations and individuals in order to assess useful,

P.596

predictable behavioural and putative emotional tendencies in a range of species. Temperament tests may assess a single behavioural tendency/trait or a range of factors to give a greater overview of the **temperament** or **personality** of animals assessed (e.g. flightiness and boldness), or of their compatibility with a particular environment (e.g. pet-owner matching).

For example, temperament tests in **pet** dogs have been used to select suitable pets from rescue centres or to identify those already in the population that are, or are likely to be, unsuitable for this particular role (e.g. those with aggressive behaviour problems). Unfortunately, many of these tests seem to have been developed without a systematic scientific approach and often excessive claims of **reliability** and **validity** are made. This is unfortunate, since the outcome of tests may be used as the basis for important welfare-relevant and even survival-related decisions. Even those that are more robust may not be feasible and so of limited value.

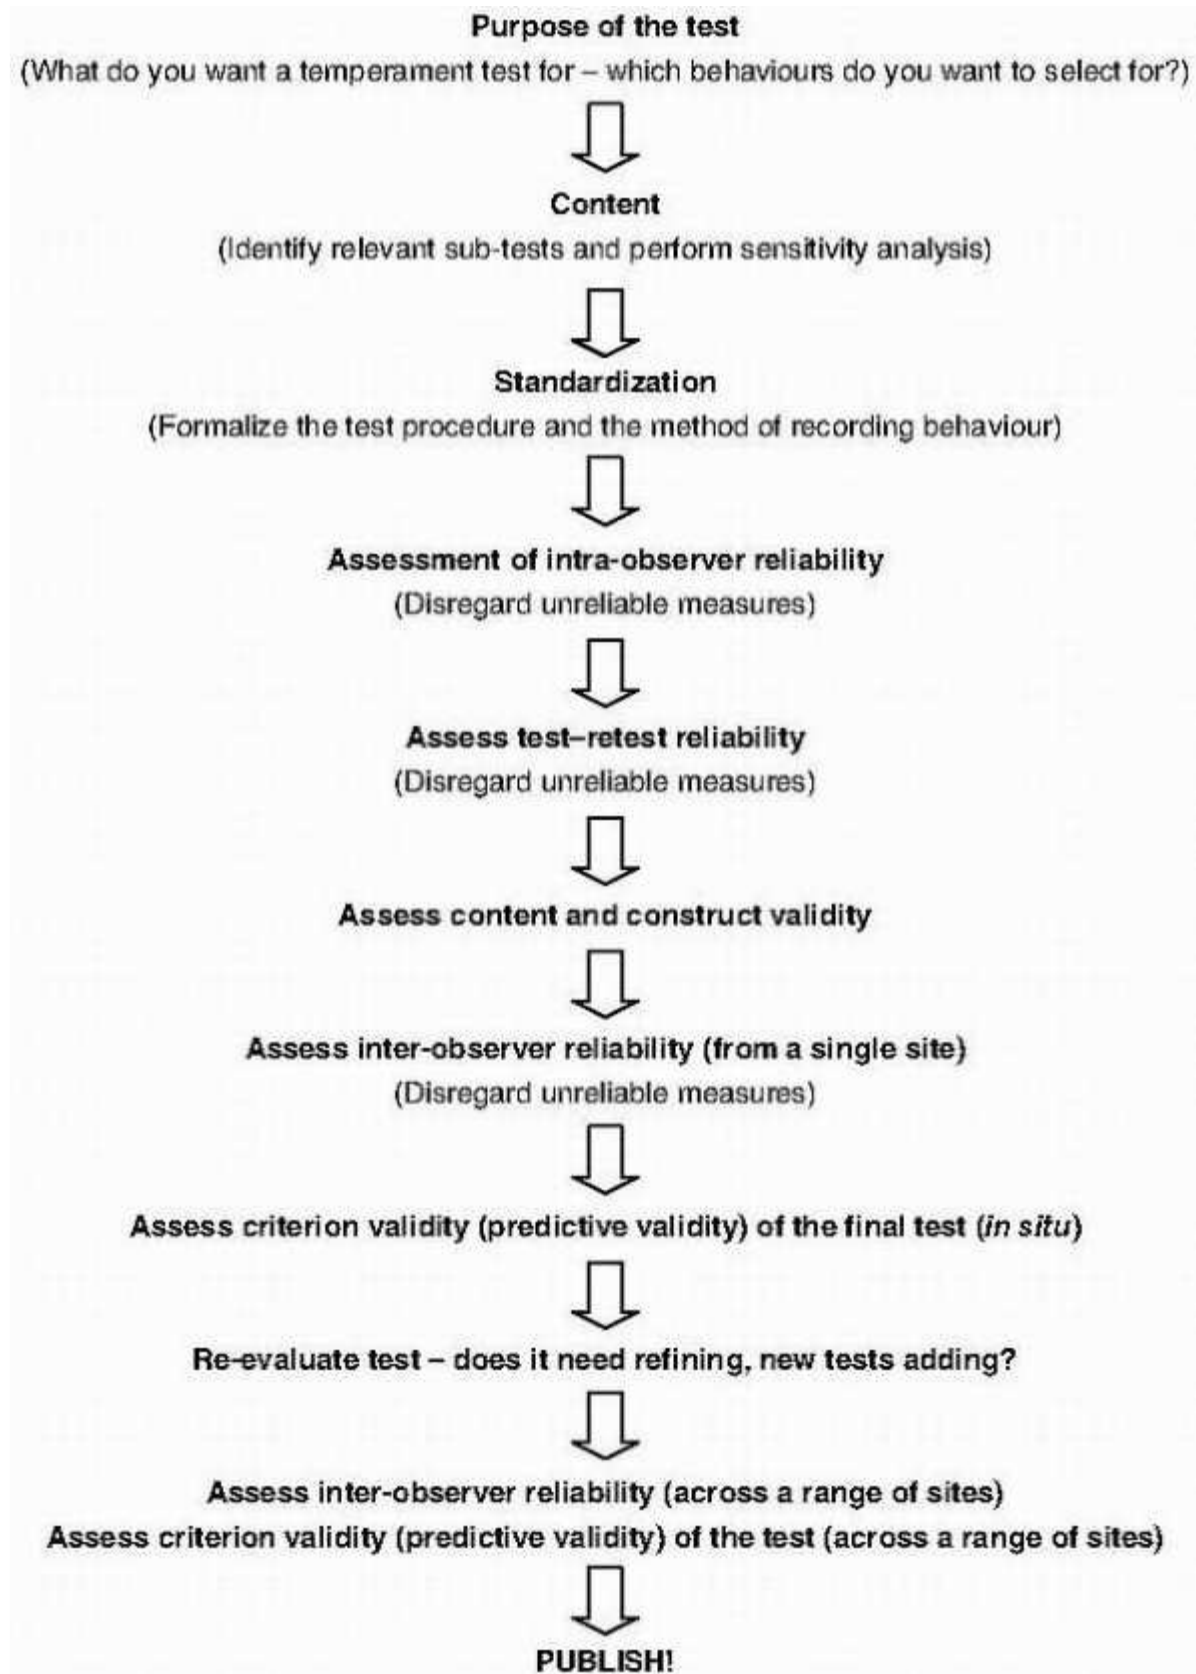

Fig. T.1. Diagrammatic representation of the process involved in creating and evaluating a temperament test (adapted from Taylor and Mills, 2006).

Reliability, validity and feasibility determine whether a given test is a good measure, the right measure and a useful measure. Reliability concerns the degree to which the test scores are free from errors of measurement. This involves identifying the consistency of the results across sub-tests, tests, observers, assessment centres, etc. Measures of reliability include consistency within the observer of the test (**intra-observer reliability**), between observers (**inter-observer reliability**), within the animal (test-retest reliability) and within components of measures designed to assess the same behaviour (internal consistency) (see Fig. T.1).

P.597

Evidence of the consistency and hence predictability of an animal's behaviour is considered by some to be what differentiates a temperament assessment from a **behavioural test**. Reliability is one, but not the only, requirement for validity. Validity concerns the appropriateness, meaningfulness and usefulness of the specific inferences made from the test results. It needs to be demonstrated that temperament tests are actually assessing what they claim, i.e. the trait(s) of interest, e.g. fearfulness, if they are to be valid. Validity assessments for temperament tests are fraught with difficulty, as it is unlikely that any test will be wholly predictive of an animal's behavioural reaction in every given circumstance. Finally, the quality of temperament tests must also address issues of practicality and appropriateness for academic or commercial use. Tests that are impractical, overly long and difficult to assess are unlikely to be performed accurately or reliably, if at all, and so a scientifically developed test will often require refinement for practical use.

For test developers two additional considerations need to be made in order that a test is reliable, valid and feasible. That is, consideration of the purpose of the test and standardization of the test procedure. If the goals of a temperament test are not clearly identified, i.e. the aspects of temperament that the testers wish to identify, then it is unlikely that the test will be valid. The next step in the development process is the selection of appropriate tests and corresponding scores for the animal's behaviour. If this stage is not standardized (formalized) then it is unlikely that the test will be reliable. It is advisable that these two additional prior requirements are fulfilled before the test developers can proceed to assessment of reliability and validity.

Teratogen

A substance that, when administered during pregnancy (particularly during the early stages, when the organs and limbs are forming), causes embryonic and subsequently fetal abnormal development. The most famous case was that of thalidomide, used in the 1960s to treat morning sickness in pregnant women, which led to a failure of the limbs to develop normally, leaving them shortened. As the limbs appeared similar in structure to those of seals, the name of *phocomelia*, literally meaning 'seal-limbed', was given to this condition. Interestingly, the thalidomide case is used by both opponents and proponents of animal testing to support their case, since some argue that it demonstrates the futility of testing while others argue that it demonstrates the need for more testing to increase confidence in safety.

Territoriality

One of the most useful general definitions of animal territoriality was developed in the middle of the 19th century, when Alfred Nobel defined a **territory** as 'any defended area'. Since then, this definition has been refined and elaborated, but not by much. These days, most scientists focus on **space** that is defended for a long period relative to an animal's lifespan, to distinguish the defence of a territory from the defence of more ephemeral **resources**, such as individual food items or basking sites. Hence, a critical component of animal territoriality is that an individual must use a particular area for an extended period of time, a pattern of behaviour called 'site fidelity'.

The second component of Nobel's definition focuses on defence. Territory defence includes a wide range of **aggressive behaviour** patterns that tend to discourage other individuals from remaining in, or returning to, a particular area; these include chases, fights and the use of jaws, claws, horns or other weaponry to inflict costs on other individuals. However, many territorial animals are able to discourage other individuals from entering space using behaviour patterns that do not have such an obvious and immediate effect on the recipients. Thus, experimental studies using tape-recordings have shown that the song of a territory owner reduces the chances that other members of the species will enter the territory, relative to their entry rates when control sounds are played from the same location. Familiar examples of territorial advertisement include the songs of birds or crickets, visual **signals** such as the push-up displays of lizards, or the scent marks deposited around the territory by wolves or rabbits.

Nobel's definition is silent with respect to the types of individuals against which a territory is defended. Years of study have shown that territory owners often make fine discriminations among different categories of intruders when defending their territories. For instance, male house mice defend exclusive territories against other dominant males, but permit adult females, subordinate males and juveniles to share their territory. In many species, territory owners behave differently when interacting with individuals with whom they share a common border (neighbours) than when interacting with otherwise comparable strangers. In some species, owners are less aggressive to neighbours than to strangers (the so-called 'dear enemy' effect), while in other species the reverse is true, and owners react more aggressively to intrusions by neighbours than to intrusions by strangers. In some animals, discrimination among different categories of intruders may even extend to selected members of other species, as in algae-eating reef fish that defend their territories against other species with similar feeding habits, but ignore species with different feeding habits.

Because the **fitness** consequences of territorial behaviour are not immediately obvious, biologists have devoted considerable attention to studying the **adaptive** significance of territoriality. One important approach to questions about territory function developed in the middle of the 19th century, when concepts borrowed from economics were applied to studies of territory function. The economic approach to territoriality assumes that individuals defend territories when the benefits of territory defence exceed the costs, where benefits and costs are both measured in terms of lifetime reproductive success.

Because, in most animals, it is difficult if not impossible to measure lifetime reproductive success, most theoreticians and empiricists take short cuts, and rely instead on indirect indices of the benefits and costs of territorial behaviour. For instance, the benefits of a **breeding** territory might be estimated by counting the number of independent young produced in a single

P.598

breeding season. Along the same lines, estimates of the cost of territory defence might rely on measurements of the number or intensity of attacks directed at intruders or neighbours, or the rate of production of territorial advertisement signals by territory owners.

One shortcoming of the classical economic approach to territoriality is that, by focusing on benefits and costs over the short term, it tends to ignore the effects of territorial behaviour on the long-term social and spatial behaviour of individuals. Most of the individuals living in the same area, because of their spatial proximity, are likely to encounter one another repeatedly over an extended period of time. This is not only true of individuals that defend territories adjacent to one another (neighbours), but also of territory owners and other types of individuals that inhabit the same area (e.g. floaters (that live in large, undefended home ranges) or intruders (that live nearby and repeatedly visit particular territories in the neighbourhood)). Whenever pairs or groups of animals interact with one another over a period of time, the behaviour of one individual at a given time can affect the behaviour of other individuals at a later time. In this situation, the behaviour of territorial animals is best analysed using the same theoretical tools that are used to study any other sort of ongoing social interactions in animals, e.g. learning-based and gametheoretical models (**see: Game theory**).

This recent theoretical framework helps explain much of the behaviour that is characteristic of territorial animals. For instance, most territorial animals exhibit the 'prior residency effect', in which residents retain possession of familiar space when competing with intruders, even if the intruders are larger, older or otherwise more competitive than the residents. Prior residency effects are predicted by a learning-based approach, which assumes that familiar space is more valuable to an individual than novel space, and that animals inflict punishment when they interact aggressively with one another. Assuming that intruders have somewhere else to go (i.e. that space is divisible), theory suggests that as long as residents can inflict some sort of costs on intruders, residents will eventually win contests over space with intruders, because the latter will eventually switch to using other areas that do not incur the ongoing costs of social interactions with residents. This prediction has been supported by empirical studies of territorial animals, showing that individuals can 'lose every

battle' but eventually 'win the war', by persistently using familiar areas and repeatedly engaging their opponent in costly social interactions in those areas.

These recent studies have interesting implications for many species of concern to applied biologists. Many species studied by conservation biologists or pest managers are territorial, and many of the species domesticated by humans are derived from ancestors with sophisticated territorial behaviour; examples include **dogs**, mice, **rats** or **rabbits**. As a result, all of these animals come equipped with the ability to respond to punishment by avoiding the individual and/or the area in which that punishment occurred and, conversely, are likely to increase their level of aggressiveness towards intruders after they have become familiar with an area suitable for long-term residency. Thus, a basic knowledge of territorial principles can be useful for managing the behaviour of these and any other animals with an evolutionary history of territoriality.

Territory

A 'territory' can be defined as an area that is defended (physically, vocally, e.g. howling or birdsong, or with **scent marking**, etc.) against a particular category of members of the same species (**conspecifics**) or the members of other species (heterospecifics) for an extended period of time. The geographic distribution of food (or some other defensible **resource**, e.g. potential mates) is an important determinant of whether an animal will defend a territory or not.

Testosterone

Testosterone is a member of the **androgen** family of hormones and, as a 19-carbon steroid, is derived from cholesterol. It is produced in relatively large quantities by the Leydig cells within the testes in males and in small amounts by the ovaries and placenta in females, and by the **adrenal gland** cortex in both sexes. Other members of the androgen family include androsterone, androstenedione and dihydrotestosterone (DHT - a testosterone metabolite). The major functions of testosterone can be described as being androgenic and anabolic. Testosterone is key for the development of secondary

sexual characteristics during puberty and the control of **libido** and certain elements of **reproductive behaviour**. It also has anabolic effects on muscle and bone.

The control of testosterone production is under strong and complex regulation. Luteinizing hormone-releasing hormone (LNRH), **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)** are known to play the crucial role here, but there are also feedback interactions with growth hormone, inhibin B and **oestrogens** that remain not clearly understood. Nitric oxide can stimulate testosterone release at low concentrations, but will inhibit release at high concentrations. There is also evidence of a neural pathway between the paraventricular nucleus (PVN) in the **hypothalamus** and the testes, which may act much more rapidly to influence testosterone release than the LH pathway.

Of particular note in the field of applied animal behaviour and **welfare** are the relationships between testosterone and reproductive behaviour, **social behaviour** (including **social stress**) and cognitive function (**see: Cognition**). Comparing species, mean testosterone levels are lower in species that are monogamous rather than polygynous. Primate species that

P.599

practise uni-male mating systems have lower testosterone levels than those that practice multi-male-multi-female mating systems. Within species testosterone levels appear to affect libido, but reproductive behaviour is also closely linked to social behaviour and the social rank of the individual and thus, social stress.

In general, a number of **stressors** have been shown to act on the reproductive system by inhibiting testosterone production. These stressors include physical and mental **stress**, **depression** and (in humans) endurance-type sport. Species studied include rats, mice, hamsters, non-human primates and humans. However, the picture is not a simple one and different types of stressors impact circulating testosterone levels to different degrees. Whereas it has been shown that chronic stress provokes a decrease in blood testosterone, the initial stages of acute stress may actually cause an increase. This is particularly the case in individuals that have a greater experience in winning agonistic social interactions and in individuals having high **dominance** in a social **hierarchy**. The type of stressor appears to be important, with agonistic interactions and sporting competition having a particularly noticeable effect. It may therefore be that these types of stressors actually induce a type of anticipation or excitement response in the individual and do not constitute a negative stress, but rather may be a positive one.

Although it is generally thought that LH is the primary driver for testosterone release, the relationships between stress, LH and testosterone are mixed. Stress can decrease, increase or leave unaltered LH levels. At the same time, studies have shown that stress may decrease testosterone without altering LH levels, or may increase testosterone yet decrease or not alter LH levels. These apparently conflicting results perhaps need closer attention in relation to the mechanisms that might exist for either lowering or elevating testosterone levels and, also, the social dominance of individuals and the effects that this might have on hormonal responses.

In general, many stressors act by inhibiting LNRH in the hypothalamus, thereby decreasing both LH and testosterone levels. It is proposed that these effects of stress are mediated by **ACTH** and **glucocorticoids** such as cortisol. These hormones are known to directly inhibit testosterone secretion by Leydig cells and also to promote apoptosis (cell death) of those cells. Stress may also initiate oxidative stress, which itself reduces steroidogenesis in the testes and can reduce blood flow through the testes.

However, also during stress, **catecholamine** release is activated and we see increasing levels of **epinephrine** (adrenaline) and **norepinephrine** (noradrenaline). Norepinephrine stimulates LH, thereby potentially stimulating the release of testosterone, but it has also been hypothesized that sensitivity to LH may be increased in the testes and thus testosterone secretion can be stimulated without a rise in LH. Regardless, 'stress' can cause physiological changes that may both stimulate and inhibit testosterone release simultaneously. Superimposed on this are the resting levels of cortisol and catecholamines in the animal prior to the stressor being applied, and the magnitude of the responses once the stressor is applied. Certainly, in the case of cortisol, resting levels can differ between animals of different social status, and the magnitude of responses of both the **hypothalamic-pituitary-adrenal (HPA) axis** and the **SAM axis** may well differ between high- versus low-ranking animals and winners versus losers. Overall, factors likely to contribute to an increase in testosterone levels as stress is applied include: (i) an absence of chronic stress; (ii) dominant status within a relatively stable social hierarchy; (iii) experience of winning; and (iv) a stress reactivity that favours norepinephrine release.

Sex hormones are known to play a crucial role in the development of the **brain**, and testosterone is also known to be present throughout life in the cortical regions of the brain that are important for cognitive processes. Androgen receptors are found in the hippocampus, prefrontal cortex and amygdale - areas that are crucial for learning and **memory** - and also, in primates, throughout the cortical regions of the brain. In rodents, gonadectomy impairs subsequent performance in maze tests, but can be normalized by testosterone dosing. In humans, testosterone supplementation has been shown to improve

spatial cognition and working memory in healthy older men, but not in younger men. In young women, a single testosterone injection can improve mental rotation and object location memory. However, there remains a great deal more research needed to clarify testosterone effects on cognition.

Tethering

Tethering is a traditional method for restraining domestic and **companion animals** such as **dogs**, **horses**, **goats** and pregnant sows (**see: Restraint**). A flexible cable, typically a rope or chain, is used to link a collar or girdle on the animal to a fixed point. This arrangement restricts the movement of the animal to a defined area.

A range of **welfare** problems can arise from tethering. These include: (i) exposure to the elements (if no shade or shelter is provided); (ii) **hunger** and **starvation** (where no food is supplied, or where the available area becomes overgrazed); (iii) thirst and dehydration (if water is unavailable); (iv) **frustration** resulting from limitations to natural behaviours and an inability to socialize with other animals (this may result in the development of **stereotypies**); and (v) strangulation due to tangling (the risk of this increases with the length of tether used). The conditions for a tethered animal can change quickly: shade moves with the sun and water buckets can easily be upturned, and the accumulation of **urine** and faeces within the range of the tether can make conditions unhygienic. The period for which an animal is tethered under inappropriate circumstances can be critical.

In response to these recognized welfare problems, the use of tethers is becoming increasingly regulated. Common aspects of legislation include: (i) the maximum time an individual animal may be tethered; (ii) provision of shelter; (iii) provision of food and water; (iv) specifications for the design of the tether (e.g. a double swivel attachment to the collar can reduce the risk of strangulation); and (v) a ban on the use of tethers

P.600

for pregnant sows. A more modern derivative of the tether uses a swivel attachment on a raised length of wire rather than a fixed point (sometimes called a running line). This increases the area available to the animal while minimizing the risk of strangulation.

Theory of mind

Theory of mind (often referred to by the abbreviation ToM) is one of the central concepts in the study of animal (**social**) **cognition** as well as in the cognitive development of children. To have a theory of mind means to understand that others have **knowledge** and a **perception** of the world which may be different from one's own, to attribute beliefs, **motivations** and desires to others and to be able to make use of that knowledge in guiding one's own actions. Knowing about the knowledge of others can be used intentionally to deceive others or to gain information from understanding and making use of information that other individuals may possess. Having a theory of mind also enables individuals to communicate with the intention to inform, and thus the sender can adapt the **communication** according to his/her knowledge about the receiver's knowledge.

The concept of theory of mind was first introduced by Premack and Woodruff in 1978. In their paper entitled 'Does the chimpanzee have a theory of mind?', they described an experiment involving Sarah, a **chimpanzee** that had been trained for more than 10 years in the animal cognition laboratory and so having long experience of interacting with humans. In this experiment, Sarah watched videos showing short sequences in which human actors were confronting different types of

problems (such as reaching for a banana outside the cage or washing a floor with a hose). Putting the video on hold before the problem was solved, the experimenters offered Sarah two different photographs: one showing the actor taking the right action to solve the problem, the other showing an unsuccessful action. More often than not, Sarah chose the photograph depicting the appropriate action to solve the problem. The experimenters argued that, in order to make such correct choices, Sarah must have been able to understand the actor's motivation.

After Premack and Woodruff's initial experiment, a large body of literature including both experimental and observational studies has been published addressing the question of whether non-human animals possess a theory of mind. There are several anecdotes of **deceit behaviour** from field observation of primates, suggesting that (at least some of) these animals are capable of using **grooming** as a way of distracting a dominant individual in order to get access to food, as well as to hide their actions from a dominant individual in order to avoid **aggression** (see Shettleworth, 1998). However, because the researchers making the observations have no information about the animals' previous experiences, it is not possible to know whether animals did use their knowledge about the knowledge and/or intentions of the other (theory of mind) or whether they behaved in a way that had been rewarded previously (associative learning), or even acted simply through chance. Carefully designed experiments are therefore essential to study theory of mind. Initial optimistic interpretations of field observations and early experiments were received by critics asking for more parsimonious interpretation, and over the course of the process, research methods have become increasingly sophisticated.

The false belief paradigm, originally introduced for studying cognitive development in children, has been widely used and adapted for use in animals. In the original set-up, a child is first introduced to a puppet. While the child and the puppet are both present, the experimenter hides a toy. Then the puppet is removed and the experimenter moves the toy to a different hiding place, still with the child observing. The child is then asked where the puppet will look for the toy. Until children are about 4 years of age, they will expect the puppet to look for the toy where they themselves know it is to be found. Young children are obviously not able to distinguish between their own knowledge and that of the puppet that has not seen the same events, and so they do not possess a theory of mind. Older children will correctly respond that the puppet will look for the toy in the first hiding place (see Shettleworth, 1998).

In different adaptations of the false belief paradigm, known as the guesser and knower paradigm, Povinelli and co-workers have tested whether primates are able to detect others' knowledge or ignorance. In one such experiment, chimpanzees were trained to gesture toward an experimenter through a hole in a transparent wall that held a food treat on the other side. When the animals had learned the task, they were tested in a series of sessions with a food treat positioned in front of two experimenters, one 'non-attending' experimenter who could not see (wore a blindfold, or held a hand or a cardboard screen in front of their eyes) and one 'attending' experimenter who could see (blindfold/hand/screen not covering the eyes but placed elsewhere near the face). A correct response for an animal that understands that seeing means knowing where the food treat is would be to reach a begging hand towards the 'attending' experimenter; however, in the experiment chimpanzees responded as often to either one of the two experimenters (Povinelli and Eddy, cited in Shettleworth, 1998).

So far, no absolutely conclusive evidence able to convince the most critical minds has been presented of theory of mind in non-human animals, although others claim that the sophisticated laboratory experiments are too artificial and distant from the animals' normal environment and communication methods and/or that all available evidence for ToM in humans is dependent on verbal affirmations that cannot be obtained in non-human animals (see Heyes, 1998 for original article and corresponding open peer commentary). Recognizing that absence of evidence is not evidence of absence, researchers are continuing their efforts to refine experiments that might be able to answer a reformulation of Premack and Woodruff's original question - 'Do non-human animals have a theory of mind?', with primates and cetaceans being the most popular candidates.

The capacities for **imitation** (the ability to learn a new behaviour through copying the behaviour of another individual) or self-recognition/self-perception (as often tested in the mirror recognition test) are sometimes associated with theory of mind. Although being able to learn through imitation as well having a concept of one's own body - as reflected in the mirror recognition test - suggests a certain level of cognition, these capacities do not require (and are therefore not evidence of) having a theory of mind.

Thermoregulation

Animals thermoregulate in various ways depending on whether they need to lose, retain or gain heat, and depending on the species. In order to *retain* heat, the circulation in the arterioles to the outer surfaces of the body is constricted. In order to *gain* heat, shivering may occur, which is a rapid constriction of the motor muscles of the body, thus generating heat from the biochemical activity of muscular contraction. Some animals may also seek shelter and huddle together, or lie on warm surfaces. In species such as rats and mice, they eat more and may build nests. To *lose* heat most animals vasodilate the arterioles to the outer surfaces and, in addition, some animals sweat and/or salivate and pant - the evaporation of the sweat and saliva decreases temperature due to the latent heat of evaporation. Many animals may seek cold surfaces and lie out flat on them. Thermoregulatory behaviour can form an important part of the assessment of the **welfare** of an animal.

Thigmotaxis

Strictly speaking, thigmotaxis refers to the movement of an organism in response to touch, but some species, e.g. rodents, are described as being thigmotactic because they appear to prefer to maintain contact with the walls of an open area when introduced into a new environment. A reduction in thigmotactic behaviour (e.g. walking along a wall) may be taken as a measure of **anxiety** reduction in the screening of drugs with this putative effect.

(DSM)

Threat postures

Threat **postures** are the behavioural displays that are typical of aggressive interactions before physical contact is made. Threat postures may be sufficient to solve a conflict or may escalate into overt **aggression**. In many species, threat postures are characterized by attempts apparently to increase body size (e.g. through fur bristling), by display of dangerous anatomical features (e.g. antlers) or by bright colorations.

(BM)

Three Rs (3Rs) principle

The principle of the three Rs (3Rs) was created by scientists William Russell and Rex Burch and published in 1959 in a book by the Universities Federation for Animal Welfare (UFAW) entitled *The Principles of Humane Experimental Technique* (reprinted 1992). Their aim was to increase the humanity of scientific research that used animals by providing a framework for scientists to use when planning their research.

It embodies the notions of *replacing* animals in research with non-sentient material, *reducing* the numbers of animals within an experiment to the minimum consistent with good statistical analysis and *refining* the experimental protocols so that the minimum of **suffering** is caused to achieve the scientific objective. These principles can be applied to any research project that involves animals where there is the potential that the animals involved may experience **pain**, suffering, **distress** or lasting harm (including **death**) as a consequence.

Although the 3Rs principle has been incorporated into some of the laws controlling the use of animals in research, including the European Directive on the Use of Laboratory Animals (86/609/EEC) and the UK Animals (Scientific Procedures) Act, both written in 1986, neither of those states the principle explicitly. This is perhaps because the principle of the 3Rs, and the

book that described it, lay largely ignored until the early 1990s, when it started to become heavily promoted by animal protection organizations such as the Humane Society, FRAME and UFAW. The book was reprinted by UFAW in 1992, and the 3Rs have now gained mainstream acceptance within laboratory animal science, both within industry and academic research. It is now expected that prior to and during ethical review of proposed harmful animal-based research, consideration of the 3Rs should be made and projects adjusted accordingly.

Centres of excellence in the 3Rs were initially created within university departments, e.g. the Netherlands Centre for Alternatives to animal use (NCA at Utrecht University) and the Center for Alternatives to Animal Testing (CAAT at Johns Hopkins University in the USA). However, national governments have now responded with the creation of national centres of excellence in the 3Rs (e.g. the National Centre for the 3Rs in the UK - NC3Rs). More recently, the European Commission has partnered with industry in the form of the European Partnership for Alternative Approaches to Animal Testing (EPAA) to help accelerate the development and acceptance of new 3Rs methods in regulatory toxicology.

Replacement

Russell and Burch defined replacement as ‘any scientific method employing non-sentient material which may, in the history of animal experimentation, replace methods which use conscious living vertebrates’.

Current important replacement techniques include cell- or tissue-based (*in vitro*) systems that use bacteria, primary human or animal cells or permanent cell lines. Examples of *in vitro* replacement tests include: (i) the Ames test to detect genotoxicity; (ii) the embryonic stem cell test to detect reprotoxicity; (iii) Hep2G human liver cells used to detect hepatotoxicity; (iv) human, blood-derived monocytes to detect bacterial contamination of biological products; (v) reconstituted human epidermis to test for likely skin irritation; and (vi) DNA microarrays to assess the direct effects of chemicals on gene expression.

Future replacement techniques are likely to involve the combination of individual, cell-based assays, even within the same system inside a microchip to build up a picture of the entire body, or the creation of miniaturized tissue organs. Other important replacement techniques include computer systems (*in silico*) and chemical-based assays (*in chemico*). *In silico* techniques include computer models that predict the toxicity of a chemical based on its similarity to others (QSARs) or computer models of physiological systems such as the human heart. *In chemico* techniques are assays based purely on the chemistry of the chemical of interest, and can include assessment of the chemical ‘reactivity’ as a measure of

P.602

allergenic potential or the use of high-tech chromatography to identify known toxins within a mixture. The latter technique is now a replacement for the detection of toxins within shellfish, a test that currently constitutes an LD₅₀ test in mice (requiring death as an endpoint for 50% of the mice injected with the shellfish mixture).

Absolute replacement includes methods that do not depend on any animal material, while relative replacement includes methods that depend on either animals of lower neurophysical **sentience** (such as insects and worms) or animal tissues. Currently, many *in vitro* cell-based replacement systems rely on primary animal tissues or animal-derived proteins, such as: (i) the Ames test, which uses proteins experimentally derived from rats; (ii) fetal bovine serum, which is obtained directly from the still-beating hearts of calves excised from their mothers at the **slaughterhouse**; and (iii) the bovine corneal opacity and permeability test for eye irritation, which uses the eyes of slaughtered food cows. There are increasing efforts to move away from these relative replacements in the interests of sound science and animal **welfare**.

Replacement techniques feature most heavily for the prediction of the toxicity of chemicals, including cosmetics and pharmaceutical drugs. This is perhaps because industry can directly appreciate the cost and time savings of replacement techniques and has been under the most public pressure to avoid the use of animals. The ban on the use of animals to test the safety of cosmetics, which entered force on 11 March 2009 in the European Union, arguably further encouraged industry to invest in alternatives. Similar incentives have yet to appear for academic research, which tends to be more variable and therefore harder to replace than regulatory toxicology. However, some important replacements have recently appeared, such as the use of non-invasive imaging scanners, e.g. functional magnetic resonance imagers (MRI) that enable researchers to ‘see’ activity in the human **brain**, rather than invasively using non-human primates.

Reduction

Russell and Burch defined reduction as the ‘reduction in the number of animals used to obtain information of a given amount and precision’.

Reduction is generally seen as something to be considered within a single experiment or procedure, known as intra-experimental reduction (de Boo and Hendriksen, 2005). However, reduction can also be an aim across an entire research project (consisting of many procedures; supra-experimental reduction) or on a much wider scale, such as something for governments and agencies to consider across entire research programmes (extra-experimental reduction).

Examples of reduction techniques include: (i) prior assessment of the required numbers of animals needed, by using pilot studies or statistical power calculations (Festing and Altman, 2002); (ii) reducing the number of concurrent control animals; (iii) usage of historical control animals; and (iv) usage of imaging machines so that disease progression and effects of treatment can be assessed non-destructively in the same animal. Harmonization of testing requirements for chemicals and medicines across countries can also be seen as a reduction exercise, reducing the numbers of animals used in what would be otherwise essentially duplicative tests.

Refinement

Russell and Burch defined refinement as ‘simply to reduce to an absolute minimum the amount of stress on those animals that are still used’.

Refinement considerations can and should be concerned with the entire lifetime experience of the animal involved, beginning with their capture or **breeding, housing and transport, handling** and cage-cleaning routines, routine veterinary care, food and **enrichment** of their cage environment, in addition to attempts to reduce the suffering involved in the procedures themselves.

Perhaps, not surprisingly, refinement efforts fall within the interest of animal welfare scientists and, with this in mind, Buchanan-Smith *et al.* (2005) recently elaborated refinement to ‘any approach which avoids or minimises the actual or potential pain, distress and other adverse effects experienced at any time during the life of the animals involved, and which enhances their **well-being**’.

Examples of procedural refinements include the use of less severe techniques, such as: (i) taking ear notches instead of amputating toes for identification; (ii) the use of **analgesia** and **anaesthesia**; (iii) training animals to cooperate with procedures; and (iv) using positive **reinforcement** such as food treats when handling.

Examples of housing-related refinements include the use of food hoppers and foraging devices, toys and platforms to encourage natural behaviour, larger enclosures including outdoor access and access to natural foraging and bedding materials. Social housing is one of the greatest contributors to positive welfare in social animals and is increasingly being considered, even if only prior to entry into a research protocol. Other positive refinements include the use of solid rather than wire **flooring**, provision of nestboxes for mice and positive human handling and **socialization**. All have been shown in studies significantly to improve the welfare of caged animals. A typically enriched non-human primate enclosure may include social housing, platforms and swing ropes, foraging devices, a varied diet, pools of water, positive handling and outdoor access.

Implementation of the 3Rs

Recent studies on the impact of the 3Rs on experimental animal research have shown mixed results. The use of animals is thought to have decreased significantly from the 1970s but is still very high, having been estimated at 115 million annually (Taylor *et al.*, 2008) and is currently, in Europe at least, no longer decreasing. This suggests that, on a macro scale, the 3Rs have yet to make any significant impact. Looking within reports of animal use within scientific journals, some authors have found that the use of pain relief has increased (refinement) and intra-experimental animal use has decreased (reduction) (Carlsson *et al.*, 2004; Richardson and Flecknell, 2005). However, specific mention of the 3Rs or 3Rs-related parameters within animal research scientific papers remains low (with the exception of animal welfare science papers), and there are suggestions coming from the animal welfare community that not only should scientific journals have ethical policies that promote the 3Rs, but that papers themselves should have sections describing the positive 3Rs changes made (Olsson *et al.*, 2007; Wurbel, 2007).

Current issues in relation to the 3Rs

Validation and acceptance of 3Rs methods

While the general aims of promoting humane research within the framework of the 3Rs are often applauded, a number of practical problems with the principle have arisen in more recent years. These include problems with the acceptance of alternative methods, competing Rs within the 3Rs and a tendency to focus on the 'easiest' R - refinement.

Significant changes to standard test procedures based on the 3Rs are often referred to as 'alternative methods'. As such, they need to be formally assessed to ensure they are reliable and provide the same results as the original test method. This process is called validation and requires inter-laboratory, if not international, collaboration. To facilitate this, Centres for the Validation of Alternative Methods (VAMS) have been created in Europe (ECVAM), the USA (ICCVAM) and Japan (JAVAM). Following positive validation statements from these bodies, new alternative tests can and (indeed, under 86/609/EEC) should be used. Current problems with this process include: (i) the lack of funding for the development of new tests; (ii) the speed at which validation projects proceed; (iii) reluctant regulatory acceptance following validation; and (iv) the obvious problems with comparing a potentially superior method with an outdated, highly variable gold standard (the old animal test), which would in all likelihood fail itself if it were to go through the same validation process (Balls and Combes, 2005).

Competing Rs

Unfortunately, as experience in the 3Rs has increased so has knowledge that each R is not mutually exclusive, and sometimes Rs can be in conflict depending on the nature of the improvement being considered (de Boo and Hendriksen, 2005). For example, the use of imaging machines such as fluorescence or infrared imagers can lead to the reduction in the numbers of animals used (positive reduction); however, it may adversely affect the welfare of those that are used in that they may be used for longer periods (across the entire disease progression) and may incur repeated handling and exposure to anaesthesia, **confinement** and pharmaceutical agents in order to be imaged (negative refinement).

Similarly, the reuse of animals across different procedures is often considered a positive reduction technique, but can have such severe refinement consequences that it may not be advocated. For example, neurophysiological experiments on non-human primates require the implantation of electro-physical recording devices in their skulls. Once implanted these can allow the animal to be used in many different research projects, avoiding the use of new animals. However, such primates are often kept confined for many years and are repeatedly exposed to behavioural experiments that none the less can cause distress.

The 'easiest' Rs

Of the 3Rs, refinement and reduction may be seen as the easiest Rs to tackle and replacement as the hardest of the 3Rs to achieve. None the less, animal protection groups would prefer animal users to focus on the replacement of animals, since this would negate the use of any animals in the future, an ultimate aim also advocated by Russell and Burch. This has led animal protection groups to criticize the 3Rs, because it allows animal users to claim discharge of their ethical responsibilities by attending to only one part of one of the 3Rs (usually refinement). This concern is reflected in the use of the word 'alternative', which has crept into 3Rs literature, confusing replacement with essentially the same animal test but with improved animal welfare. For example, the fixed-dose procedure is seen as an alternative to the notorious LD₅₀ test for acute toxicity. There is no doubt that the fixed dose represents a significant improvement in animal welfare, not requiring the death of 50% of the animals, but nevertheless it remains a very serious animal procedure.

There is a danger in considering that implementation of the 3Rs is all that is required when considering the use of animals in harmful research. Assuming full replacement is not possible, the harm versus benefit of the research should also be assessed. This assessment should weigh up the harms done to the animals (after the 3Rs have been applied) against the potential benefits of the resulting research. The benefits of the research should be considered, not just in terms of knowledge gained but also for the quality of the research and the likelihood of it producing positive improvement to human or animal health. For example, even though researchers may make positive 3Rs improvements to these tests, it could be argued that using animals in cosmetics or household product testing should not be allowed because the impact on human health is trivial. Similarly, testing of chemicals for carcinogenicity should arguably not be permitted given the known limitations of the rodent model of cancer. To this end the 3Rs can be seen as a 'reactive' solution to be applied *after* the genuine need to perform research on animals has already been decided.

Therefore, while the 3Rs principle provides a useful framework for seeking to improve animal-based research, applying these simple rules should not negate other important ethical and scientific considerations that should be made before the harmful use of animals is even considered.

Thyroid hormone

There are two thyroid hormones produced and secreted by the thyroid gland, these being thyroxine (T_4) and triiodothyronine (T_3). Thyroxine and triiodothyronine are produced from tyrosine, having either four (T_4) or three (T_3) iodine atoms on the thyronine ring. Low dietary intake of iodine will lower the production of these two hormones.

The production and secretion of these hormones are initiated by the **hypothalamus**, which secretes thyrotropin-releasing hormone (TRH), which enters the hypophyseal portal system to reach the anterior **pituitary gland** to bind to membrane receptors on thyrotrophs - cells in the anterior pituitary that produce thyroid-stimulating hormone (TSH); the anterior pituitary gland then produces and secretes TSH. Upon thyroid stimulation, thyroglobulin - which is the storage form of T_3 and T_4 - is transported from the lumen of the follicle, by pinocytosis, into the follicular cells of the thyroid gland. In these cells the large protein, thyroglobulin, is hydrolyzed into T_3 and T_4 and secreted into the peripheral circulation. The majority of thyroid hormone produced and in circulation is T_4 . The majority of T_3 and T_4 concentrations are then bound by thyroxine-binding globulin, while the remaining 30% is bound to albumin or thyroxin-binding pre-albumin. Only a fraction of 1% remains unbound in the peripheral circulation. The large percentage of bound hormone supplies the body with a large pool from which to draw and prevents its degradation until it reaches its target tissue.

Of the two thyroid hormones it is T_3 that is considered the biologically active hormone, although T_4 to a lesser extent can bind to thyroid receptors. After entering the peripheral circulation, T_4 is converted into T_3 in organs such as the anterior pituitary gland, the kidney and the liver. Most tissues in the body have nuclear receptors for thyroid hormone, and by activating these receptors thyroid hormones set the basal rate of heat production and oxygen consumption for an animal. Thyroid hormones also influence the rate of lipid, protein and carbohydrate metabolism, increasing these rates when thyroid hormone concentrations are elevated and decreasing them when thyroid concentrations are low.

Overall secretion of thyroid hormone is regulated by a negative **feedback** system, in which high concentrations of circulating hormone cause the anterior pituitary gland to decrease production of TSH and thus decrease the production of thyroid hormone. Thyroid hormone is particularly important in the processes of physical and behavioural maturation, as well as in cognitive development (**see: Cognition**), and differences in thyroid hormone effects have been suggested as one of the factors controlling neoteny.

Thyrotropin-releasing hormone

Also known as either TRH, thyrotropin-releasing factor or TRF, this is a peptide hormone produced by the **hypothalamus** that stimulates the **pituitary gland** to produce the peptide thyroid-stimulating hormone (TSH, or thyrotropin), which itself regulates the production of thyroid hormones. Its action is antagonized by growth hormone-inhibiting hormone. The relationship between TRH and welfare is complex and depends on the specific **stressor** and species concerned. TRH can also stimulate **prolactin** production.

Tid-bitting

Tid-bitting is a behaviour performed during courtship displays in many species of galliformes, in which the male pecks repeatedly at the ground to attract females. During this the cock may also scratch and give food calls. The behaviour may also be performed as a threat during **competition** between males. Tid-bitting is also performed by female birds, which will peck at a food source to attract their chicks to it.

(RJNM)

Time budget

Time budgets measure the amount of time animals spend performing various behaviour patterns, and are often measured over 24 h periods. Some behaviours may occupy a large amount of an animal's available time while others may take very little time to perform, but this does not necessarily reflect their relative importance. Time can be thought of as a commodity, as only a finite number of activities are possible during a set period of time. Thus an animal may modify the amount of time spent performing different behaviour patterns depending on the time and behaviours available. For example, when the milk supply of deer fawns was reduced, their time

P.605

spent **nursing** also decreased but their time spent **grazing** increased to compensate for the change in nutrition.

The way animals behave throughout a period of time can be viewed as the result of a series of **preferences** or choices between different behavioural options. In **wild animals**, the daily time budgets followed can be seen as strategies for **coping** with environmental changes, such as increases or decreases in food availability or variations in temperature. Allocating the appropriate amount of time to different behaviours and performing these behaviours at appropriate times of day will affect an animal's ability to survive and reproduce. Factors that affect the amount of time spent on different behaviour patterns include food reserves, risk of **predation**, time available to perform the behaviour and the results of behaviours performed earlier.

Time budget measurement can be used as a tool to assess animal behaviour and evaluate **welfare**. Resources or environments can be manipulated and the effects on different behaviour patterns can be recorded (**see: Economics of behaviour**). Time budgets of wild and captive animals can also be compared to determine the potential effects **captivity** may have on behaviour (Veasey *et al.*, 1996). As measuring time budgets requires only recording of the start and stop times of certain behaviour patterns, it is an easy technique to implement. It can be done through live observation or through video-recording and measuring time budgets from tapes. Thus, it does not require any expensive or elaborate equipment.

However, there are problems with using only time budget measurements. While measuring time budgets can determine how behaviour is affected by different factors, a difference in the amount of time spent performing a behaviour pattern does not necessarily indicate deprivation or **suffering**. The behaviour may be strongly dependent on external cues and is not shown in situations where the cue is not present. For example, anti-predator behaviour is commonly found in wild species and is important to survival and **reproduction**. However, in captive environments, where predators are not present, anti-predator behaviour is not important and thus rarely shown. In addition, some behaviour patterns may be performed when possible but the animal does not suffer if the behaviour is prevented, i.e. the animal *wants* to perform the behaviour but does not *need* to perform the behaviour.

One way around these constraints has been devised by placing costs on the performance of certain behaviour patterns and measuring what happens as the costs increase. In other words, the animal's **motivation** to perform certain behaviour patterns is measured. These methods have been adapted from human economics and are generally referred to as consumer demand experiments. As part of these experiments, the time devoted to performing certain behaviour patterns can be measured as it becomes harder and harder to perform the behaviour. If the amount of time devoted to a behaviour pattern decreases as costs increase, the behaviour is thought to be less important to the animal. However, if the time devoted to performing a behaviour pattern remains fairly constant as the cost increases, the behaviour is thought to be important to

the animal. Alternatively, the amount of time available to perform a range of behaviours can be decreased (cost) and the animals will reschedule their behaviour patterns to allow more time to be spent on the more important behaviours.

Consumer demand techniques are not without their own problems (**see: Preference test**). Thus, care should be taken when designing these types of experiments to avoid or compensate for as many problems as possible.

Tinbergen, Nikolaas (Niko)

Niko Tinbergen (1907-1988) was born in The Hague, Netherlands, on 15 April 1907 and studied at the University of Leiden, where he was awarded his PhD in 1932. Together with **Konrad Lorenz** and **Karl von Frisch**, he was awarded the Nobel Prize for Physiology or Medicine in 1973. He first met Lorenz in 1936 when he was invited to lecture at Leiden, and the two soon became close friends and colleagues, with Lorenz traditionally being seen as the scientific speculator and Tinbergen the more analytical scientist.

The two became separated by World War II and Tinbergen, like Lorenz, was held hostage during some of this time. After the war he was invited to set up a behaviour research group at Oxford, UK, and this ultimately led to his reunion with Lorenz. Perhaps his most enduring legacy is what has become known as **Tinbergen's Four Questions**, which outline four approaches to the study of animal behaviour relating to proximate and ultimate factors: namely its physical mechanism, lifetime development, **evolution** and **adaptive** function. Tinbergen was notoriously modest about his abilities and, in addition to being a formidable scientist, was also an accomplished illustrator.

Tinbergen's Four Questions

In 1963, **Niko Tinbergen** wrote 'On the aims and methods of ethology', and proposed what are now referred to as Tinbergen's Four Questions. These questions, based in part on previous suggestions by Ernst Mayr, have helped guide behavioural research for the past four decades. These four logically distinctive and mutually exclusive types of questions about causation, development, **adaptive** utility and evolutionary history can be profitably applied to any bio-behavioural phenomenon. Importantly, by asking questions at multiple levels of analysis, our knowledge about behaviour is enriched. Broadly, a bio-behavioural question could focus on how something works, or why it is as it is.

Proximate questions are those employed to explain how something works or how it develops. For instance, studies of functional morphology tell us how behaviour is patterned and its structural basis. Studies of behavioural genetics identify the degree to which genes are responsible for behaviour, and the

field of genomics identifies those genes. Studies of behavioural endocrinology tell us about the hormonal control or regulation of behaviour. These three examples illustrate causal questions. By answering them, we learn about how behaviour functions. A logically distinct type of proximate question focuses on the development (or **ontogeny**) of behaviour. Ontogenetic questions might ask about the degree to which a particular behaviour requires specific experiences to be properly performed, and address the time course of development.

Ultimate questions are those employed to explain why we see the diversity of behaviour. For instance, studies that focus on the **evolution** of behaviour tell us how or when a particular behaviour evolved. They might also tell us how many times a behaviour evolved. To do so, evolutionary biologists construct phylogenetic trees (hypotheses about the relationships between species) and then ‘optimize’ (i.e. map) behavioural traits on these trees. A logically distinct type of ultimate question focuses on the current adaptive utility of a trait. Only traits that increase the **fitness** of individuals who possess them will evolve or be maintained by natural **selection**. For instance, if long legs aid in escaping predators, we will expect natural selection for leg length and running speed to evolve.

Importantly, these four types of questions (or levels of analysis) produce questions that are mutually exclusive only within a level. Consider birdsong: we can ask about the evolutionary history of song learning. Song learning has evolved in parrots, hummingbirds and passerine birds. Among passerines, it is seen in a broad group called the oscine birds. These are questions about the evolutionary history of birdsong. We can also ask about the current adaptive utility, or function, of birdsong. Male birds may sing to attract females or to defend their **territory** from other males. In some species, males that sing more songs have more mates and therefore have higher fitness. It would be illogical to use evidence that, because male birds sing to defend territories, song learning has evolved only once. Questions within a level of analysis are mutually exclusive only with other questions within that level.

We can ask proximate questions about birdsong as well. For instance, recent work on the genetics of song has discovered that humans and birds both express the *FoxP1* and *FoxP2* genes. In birds, these genes are specifically expressed during song learning. A set of **neuron(e)s**, called the higher vocal centre (HVC), seems to be responsible for the neural control of song learning. In some species, the size of the HVC is correlated with the number of songs they produce, while in other species the size of the HVC changes seasonally and becomes largest when song learning is required. Finding evidence that the HVC does not change seasonally has no direct bearing on whether or not *Fox* genes are expressed during song learning; nor does it directly bear on hypotheses about the evolution of song-learning abilities, or about whether or not males that exhibit larger repertoires have higher fitness. Again, these questions are mutually exclusive.

By taking a Tinbergenian approach to studying behaviour, it forces us to examine qualitatively different sorts of questions. By doing so, we generate considerable knowledge about the diversity of behaviour. Recognizing that these are qualitatively different questions is essential, as well as ensuring that arguments about explanation are contrasting different hypotheses at the same level of analysis.

A fifth question to help extend the scope of behavioural research might also be proposed: What is the applied value of a trait or phenomenon? Formal recognition of a fifth question has several benefits and no real costs. Virtually all questions can be applied in some way and, by recognizing the applied value of a phenomenon, we expand the scope of inquiry. Much, but not all, applied research asks proximate questions, but these questions are targeted to address a larger question. For instance, researchers who study animal **welfare**, **conservation** biology and **comparative psychology** routinely apply the results of their studies to non-humans or to humans to increase welfare, manage wild or captive populations or to understand the biological basis of human behaviour. In many cases, the applied benefits of a study are the central question.

Not all researchers will desire to apply behavioural knowledge, just as not all evolutionary biologists are interested in studying proximate questions about causation. This, in itself, is no reason not to recognize the study of applied behaviour as a formal, logically distinct field of enquiry. It is essential to value high-quality research at whatever level of analysis it is conducted and not to dismiss the importance of focused studies operating only at a single level. By formally testing hypotheses about application, we can clearly identify applied benefits and this may help ‘market’ behavioural research to the public. Formal acknowledgement of the applied value of behaviour should make the future of bio-behavioural study even richer.

T-maze

A T-maze is an apparatus employed to examine spatial memory in animals. The animal is placed at the bottom of the T-shaped apparatus in a start box, is required to move along the apparatus and then to turn either left or right to reach a reward. After that the animal is taken back to the start box, where it is retained for a period of time (termed the retention interval). At the end of the retention interval the animal is released and allowed to search for the reward. There are several types of tests. For example, in a match-to-sample procedure, the animal has to choose the same arm that it visited recently in order to receive a reward. In a non-match-to-sample procedure, the animal has to choose the alternative arm to the one last visited.

Knowledge of animals' spatial **memory** abilities is necessary in many species and, in particular, for farm animals in extensive production systems, since such animals would need to locate and exploit distant resources. For example, laying hens in large systems are not always in sight of resources such as food, water, litter and nestboxes, and may need to remember the location of these resources, as well as to navigate to them. Clearly, a failure to find resources would severely compromise the **welfare** of animals in production systems.

Research involving T-mazes, and also other apparatuses such as radial-arm mazes, has proved invaluable in investigating

P.607

spatial memory in animals, and hence identifying potential cognitive deficits which would impinge on welfare (**see: Cognition**). For example, Mendl *et al.* (1997) investigated the effects of rearing pigs in both a substrate-enriched and a substrate-impooverished environment on their performance in a T-maze, and concluded that substrate-impooverished environments provide inadequate stimulation for the expression of their natural behaviour.

Mendl, M., Erhard, H.W., Haskell, M., Wemelsfelder, F. and Lawrence, A.B. (1997) Experience in substrate-enriched and substrate-impooverished environments affects behaviour of pigs in a T-Maze task. *Behaviour* 134, 643-659.

Tongue rolling

Although it occurs rarely, the most common stereotypy among adult **cattle** is tongue rolling; it is also found in many other captive species, notably **horses** and **pigs**, when they are subject to marked **confinement**. The behaviour involves repetitive, circular movements of the tongue inside or outside of the mouth. Among adult dairy cows, tongue rolling occurs more frequently when the animals are tethered, rather than being loose housed, but the method of feeding is more important than the way cows are housed.

Tongue rolling in cows occurs most when they are fed a small amount of food. Adding straw to cows' diets reduces tongue rolling, even though the energy content of the diet is not significantly altered. By transferring ruminal content between cows (using ruminal fistulas), researchers have shown that tongue rolling in cows occurs most when they can eat only a small amount of feed, during a short period of time and have low ruminal content after the meal. Tongue rolling occurs also in young calves and fattening bulls. Providing calves with more water or increased fibre, or with objects that they can suck or chew, such as a piece of rubber tyre or a chain, reduces tongue rolling. There has been little scientific investigation of tongue rolling in horses, but it may be that its occurrence relates to similar factors.

There are large differences between animals in the extent to which they show tongue rolling; most individuals show little or no tongue rolling, while a small number perform the behaviour frequently. Little is known about the individual differences that underlie this. There are few clear relations between the occurrence of tongue rolling and signs of **stress** or production levels in farm animals, and the relation between tongue rolling and animal **welfare** is uncertain.

Tonic immobility

Tonic immobility is an unlearned response to a brief period of physical **restraint** and is characterized by a reduced-reactivity, 'catatonic-like' state (Jones, 1986). Tonic immobility can also refer to the seemingly immobile state, or 'freezing', response to the presence of a predator or other dangerous stimuli. It was initially characterized in 1636 by Daniel Schwenter, and has since been referred to by several different names including **death** feigning, animal hypnosis, catalepsy and fright paralysis. Tonic immobility response has been characterized in many invertebrate and vertebrate species. It is most commonly used and best defined in bird species, including domestic fowl. Although there is no loss of **consciousness**, animals in a state of tonic immobility appear to be in a hypnotic state, remaining virtually immobile with suppressed respiration and body temperature. Altered **heart rates**, decreased movement and **vocalization**, and muscle rigidity are also common. The animal is not entirely immobile, however, because tonic immobility is also marked by muscle tremors in the extremities, spontaneous eye movements and jerking or bobbing movements of the head and neck.

There are two well-accepted definitions of tonic immobility: the first includes two stages of tonic immobility (Jones and Faure, 1981) and the second defines this phenomenon as having three levels (Rovee and Luciano, 1973). The two-stage definition includes the initial stage that lasts from the induction of tonic immobility until the first vigilant movement of the head. This first stage is marked by severe suppression of alert activity; however, it may include muscle tremors or jerking movements of the extremities and spontaneous movement of the eyes and head. The second stage continues from the first attentive head movement until the animal rights itself. This stage is marked by vigilant head movements and may consist of increasing frequency of leg movements and vocalizations.

The three-level definition describes tonic immobility by the level or degree of immobility or awareness. An animal in level one of tonic immobility has open eyes and generally makes loud vocalizations. This level is reached immediately at the onset of immobility and again just before its cessation. At level two, vocalizations are reduced and the eyelids flutter open and shut. The third level is marked by cessation of all vocalizations and movements, with the exception of jerking movements of the body and extremities and characteristic head bobbing. An animal in level three of tonic immobility also maintains closed eyelids.

In a clinical setting, tonic immobility is generally induced with brief physical restraint, often lasting only between 10 and 30 s, being applied to the animal in order to induce tonic immobility. The protocol for physical restraint varies within and across species. In avian research, the bird is typically laid upside down in a U- or V-shaped cradle and restrained by light pressure on the sternum for a brief period (approximately 15 s). Piglets are also often laid upside down in a U- or V-shaped cradle while the experimenter places a cloth bag filled with sand on the piglet's chin, to stretch its head back, and the piglet's legs are stretched gently back to induce the immobility response. However, animals may also be laid on a flat surface with or without cushioning, or in an induction box, and may be laid laterally, ventrally or dorsally. After this initial restraint, the animal voluntarily remains in the characteristic catatonic-like state for a varied period of time afterward.

Measures taken generally include: (i) number of inductions required to achieve the immobile state; (ii) time to first

involuntary head movement; (iii) number of involuntary head movements; and (iv) duration time of tonic immobility or the latency time before the animal rights itself. Tonic immobility responsiveness, including duration of immobility, may vary with the induction protocol used, including the orientation of the animal during induction. As the majority of tonic immobility experiments are performed by laying the animal dorsally, it had been suggested that the disorientation associated with tonic immobility may be due to inner ear involvement. However, vestibular involvement seems unlikely as tonic immobility may also be induced laterally and ventrally. Additionally, research performed on frogs following surgical removal of the ears showed that altered frogs performed similarly to intact frogs on tonic immobility tests.

Tonic immobility responsiveness, including ease or ability to induce and duration of immobility, is used to assess an animal's fearfulness, as tonic immobility has been shown to be positively correlated with an animal's fearfulness. Animals that

showed prolonged tonic immobility durations or lesser inductions required to induce tonic immobility also scored higher in **fear** response to such fearfulness tests as **novel object tests** and environment tests. Tonic immobility has been suggested as being a superior measure of fearfulness that overcomes some of the pitfalls of the more traditional fear tests. The uniformity that tonic immobility affords, both between investigators and between animals, provides reduced individual variability. Specific tonic immobility protocols, like that published by Jones (1986), allow for the test to be performed similarly by multiple experimenters. Compared with many fearfulness tests, **memory** and past experience have less of an effect on the test results. However, the degree of fear that the protocol for induction and the tonic immobility itself elicits is currently unknown. Alternatively, fear alone does not elicit an immobile response.

Physiological studies have been performed to assess the relationship between tonic immobility responsiveness and the fear elicited by the test. Fear-eliciting stimuli increase respiration and heart rate. It has been shown that respiration rate increased with induction of tonic immobility, suggesting a possible increase in fear responsiveness. Following induction of tonic immobility, respiration rate decreased steadily for the duration of the immobility response. Heart rate, however, has been studied in more depth and lends less convincing evidence of the fear-inducing quality of tonic immobility. Numerous studies of the effect of tonic immobility on heart rate have yielded inconclusive results. However, the most recent studies suggest that the test provokes an increase in heart rate, reflective of increased plasma concentrations of **catecholamines** in response to **stress** or fear, immediately following the initial restraint of the tonic immobility protocol. These studies also found a fall in heart rate, significantly below the pre-induction rate, following the initiation of immobility. It has been suggested that the inconclusive results of previous studies may be due, in part, to the technological inability at the time to obtain heart rate measures without adding additional fearful stimuli to the immobility protocol.

The process of inducing tonic immobility has been shown to elicit a stress response in several species. Induction of tonic immobility in Japanese quail has also been shown to be marked by an increase in plasma **corticosteroid** levels compared with pre-induction levels, suggestive of increased physiological stress. Similarly, strains of Japanese quail bred for high and low stress, as measured by high and low corticosterone response to a brief mechanical restraint, exhibited greater and reduced fearfulness, respectively, as measured by the tonic immobility test. Domestic fowl showed increased tonic immobility duration following continuous infusion of corticosterone by mini-pump (15 mcg/h) for 4 and 11 days. Hens from a strain of white Leghorn bred for long duration of tonic immobility were also shown to have higher heterophil/lymphocyte ratios than birds bred for a short duration of tonic immobility. Increased heterophil/lymphocyte ratios suggest an increase in stress and reduction in immunocompetence. Studies have shown a positive correlation between tonic immobility responsiveness and the degree of fluctuating asymmetry, a measure of chronic stress. Similarly, strains of hens with reduced stress-coping ability have also been shown to have increased latency to the first head bob and overall tonic immobility duration, as well as reduced inductions required to elicit immobility.

Tonic immobility is apparently similar to a hypnotic or sleeping state. Reduction in both respiration and heart rate suggests a possible physiological similarity between the two states. Further evidence, however, has shown a marked difference between tonic immobility and **sleep**. Electroencephalographic (EEG) activity was measured from the hippocampus of **rabbits** during periods of movement, non-movement, tonic immobility and sleep, results showing that rhythmic, slow activity was identical during tonic immobility to that during periods of non-movement and was increased only during periods of movement and active sleep.

Tonic immobility responsiveness has also been linked to other behavioural strategies. It has been suggested that reduced tonic immobility responsiveness may indicate a more active or bolder behavioural strategy. Piglets that did not become immobile after experimental attempts to induce tonic immobility also exhibited more active behavioural strategies, such as shorter emergence times from a test box. Contrarily, white Leghorns exhibiting high aggressiveness also maintained longer tonic immobility durations compared with less aggressive birds. Strains of Japanese quail bred for long tonic immobility duration were found to struggle more than birds bred for short tonic immobility duration (**see: Coping**).

The evolutionary origin of the tonic immobility responsiveness is not completely known. However, it appears to be an adaptation in surviving predatory attack. When restrained by a predator tonic immobility, or feigning dead, increases the chance of survival. It has been shown that tonic immobility duration increases in the presence of a predator simulation. It has also been shown that birds and mammals in the wild increase their chance of surviving an attack when they succumb to a state of tonic immobility following the initial attack of a predator. It is common that predators, such as **cat** and **dog** species, will temporarily release their hold on their prey once they become immobile and, in some instances, even walk away from their prey completely. Immobility or freezing in the sight of a predator might also lessen the chance of initiating an attack. Although freezing might reduce the chances of attracting the attention of a predator, it is also possible for an animal successfully to flee, thereby escaping attack, especially if the animal is a considerable distance from

the predator. It has been shown that the distance to the predator is negatively correlated with the ability to induce tonic immobility and the duration once the animal is induced.

Tonic immobility responsiveness can be affected by many environmental factors, including time of day and age of individual. Extensive research on the diurnal periodicity of the immobility duration in domestic fowl showed that the shortest tonic immobility duration occurred immediately before and after the onset of the light cycle. The longest duration however, was most often observed at mid-day, 5-7 h after lights on. The evolutionary explanation for this **diurnal rhythm** is not entirely clear; however, it has been suggested that it may reflect the periodicity of predatory attacks. The evidence for age effects on tonic immobility response is less clear. Some studies have found that animals, including white Leghorn chicks, do not acquire the tonic immobility response until 1 week or so of age, while contrary evidence has shown that white Leghorn chicks can be induced less than 24 h post-hatch.

Researchers have suggested that animals may reduce their tonic immobility responsiveness with age. However, it has also been suggested that repeated inductions or taming by regular handling were confounded with age and may have had a greater impact on reducing tonic immobility responsiveness. Further studies have confirmed a **habituation** to repeated inductions. Consistent handling has also been shown to reduce tonic immobility duration, as well as to suppress fearfulness to humans and novel environments.

Social environment has also been shown to influence the immobility response. White Leghorns housed in isolation have been shown to have increased fearfulness and tonic immobility duration compared with **group**-housed hens. However, in group-housed hens, **dominance** position has been shown to affect tonic immobility responsiveness, with subordinate birds exhibiting shorter durations compared with their dominant counterparts. Birds maintained at high stocking densities (**see: Stocking density**) showed increased fearfulness, as evidenced by increased immobility durations compared with birds maintained at lower stocking densities. Birds housed in groups with 50% of birds marked for identification showed reduced inductions required to achieve tonic immobility compared with birds from groups where all birds were marked. Tonic immobility response is also affected by **housing** and physical environment. Domestic fowl have been shown to have longer duration of immobility in tonic immobility tests when housed in cages compared with those housed in more spacious aviaries. Similarly, birds housed in floor pens exhibited significantly shorter tonic immobility durations compared with birds housed in conventional cages.

The presence of familiar objects, **conspecifics** or people during testing has been shown to reduce the tonic immobility duration. Although the presence of humans can elicit a fear response in most animals, the degree of familiarity the animal has to a specific human is negatively correlated to the degree of fear that human elicits. Additionally, research animals in some circumstances have been found to imprint to an experimenter. The presence of a human to whom an animal has imprinted will elicit a considerably suppressed fear response (**see: Imprinting**). Use of the same experimenter for induction is ideal in order to reduce the confounding effects on tonic immobility response from familiarity with the experimenter. Different experimenters also exhibit differences in the roughness of handling, which can also alter the latency time before the animal rights itself. The presence of novel objects, predators, loud noises and increased light have been shown to increase latency time before the animal rights itself.

The tonic immobility response can also be used to immobilize an animal for other tests and measures without the use of pharmaceuticals or continuous manual restraint. Mechanical and pharmacological methods of restraint can be considered contrary to good welfare of the animal. They can also cause **injury** and **pain** and elicit chemical responses that might interfere with the experimental results. The use of the tonic immobility phenomenon to immobilize the animal may be a cost-effective and welfare-efficient animal handling technique.

Tool use

Tool use is first evidenced in the hominid fossil record about 2.6 million years ago, and was originally thought to be a defining feature accompanying the emergence of the genus *Homo*. *Homo habilis* (or 'handy man') possessed a larger **brain** than their predecessors, the australopithecines, and the correlation between the two traits led early physical anthropologists to postulate that an increased brain size was directly related to the development of complex behaviours such as tool use. At the time of these discoveries the humancentric view of 'man the toolmaker' was widely accepted; it was several years later in the early 1960s when Louis Leakey appointed a young Jane Goodall to conduct a study of **chimpanzees** in the wild. Goodall was one of the first people to witness tool use in non-human primates, at Gombe in Tanzania, when she saw one of her study animals dipping for ants using a twig, which had been modified by stripping it of its leaves.

Tool use can be loosely defined as the manipulation of an object to perform a specific task. It may often involve modification of existing materials in an apparently purposeful way to perform a function that cannot be accomplished without the tool for a beneficial effect, such as exploiting different foods. The significance of tools is, by extension, what they can tell us about the cognitive abilities of the toolmaker and user. For example, stone hammers may show little modification of the raw material but chimpanzees show a degree of foresight and planning when using them, carrying

P.610

favoured stones hundreds of metres to the nut-cracking site. Knapping of stone tools by early hominids produced stone fragments that have proved invaluable to archaeologists trying to reconstruct early human material culture - recent interest in chimpanzee tool use behaviour has shown that their culture too leaves traces in the archaeological record (that might be mistaken for human artefacts).

Since the earliest ethological studies confirmed that chimpanzees use tools, their deployment has been witnessed in all three remaining species of **great ape**. **Gorillas** were first seen to use water in spectacular splashing displays in 2001, but it was not until 2005 that a female gorilla was captured on film using a branch to test the depth of water in a murky pool that she later crossed, using the same branch as a walking stick. One of the first instances of tool use by **orang-utans** was unexpected - after 9 years of fieldwork an adult male was observed to select a dead branch to scratch his rear in 1976. It was not until 1994 that Carel van Schaik recorded instances of orang-utans using thin sticks to poke into the centre of fruits covered in irritant hairs to extract the seeds and pulp, and the variety of tool use behaviours observed has increased since then. Bonobos have not been observed to use tools in the wild but, as with other species of great ape, they are prolific tool makers and users in both **captivity** and populations that have been reintroduced into the wild. Tool use is generally more prevalent in captivity rather than in the wild, even when corrected for observational bias. This is at least in part due to the increased opportunities for experimentation in captive environments, where basic biological needs are met easily and, additionally, suitable objects may be deliberately made available to the animals in question.

Tool use is not restricted to apes - capuchin **monkeys** in the Caatinga forests of north-eastern Brazil use stones to dig for tubers, to crack hard seeds and to pierce hollow branches to access food during the long dry season. The earliest anthropologists would have been even more incredulous to discover that the New Caledonian crow (a species restricted to a Pacific island archipelago) has shown expertise in the production of complex tools that are selected for different food-finding tasks, and shows a level of innovation that may exceed that of chimpanzees. A wide variety of other animal species can be regarded as tool users exhibiting varying degrees of competence in the selection, manufacture or fashioning of tools and degree of cognitive insight, including Galapagos finches, green herons, Egyptian vultures, sea otters and bottlenose dolphins.

Culture can be defined in a biological sense as intergenerational transmission of **group**-specific behaviour at least partly acquired from **social learning**. We know very little about cultural variation in tool use repertoires among species other than humans and chimpanzees. Chimpanzees in West Africa, east of the Nzo-Sassandra River in Côte d'Ivoire, habitually use stone or wooden hammers and anvils to crack open hard-shelled nuts to extract the nutritious seeds within. Chimpanzee populations to the south and east of the Sanaga river in Cameroon, however, have not been observed exhibiting this behaviour (despite all the necessary materials being present) in spite of decades of behavioural studies by researchers. Between these two regions, however, the behaviour is not consistently present or absent, and it seems that this particular behaviour may have evolved on several occasions, or else it has become extinct in some areas since its invention. It has been suggested that stone tool use in capuchins has developed to exploit different foods due to the harshness of the long dry seasons, so resorting to an ecological explanation of the invention of a culture. This explanation for the invention of a culture is not so obviously reconcilable in the chimpanzee example, however - there are few ecological differences between habitats where chimpanzees do and do not crack nuts in West-Central Africa.

That tool use is evident in a diverse array of taxonomic groups throughout the animal kingdom should not detract from its emergence as a vital factor in the evolution of humankind's behavioural repertoire. Humans have gone further than their closest living relatives in the manufacture of a complex tool assemblage - insights from the other proficient tool users are invaluable in understanding the development of our own tool-using culture.

Tooth

A tooth is a structure embedded in the jaws of animals that may be used for eating, **grooming** and defence. Many animals have teeth of different sizes and shapes, a condition known as heterodonty, allowing different teeth to be specialized for different tasks. These specialized teeth can be categorized into four different types, including incisors (I), canines (C), premolars (P) and molars (M), although not all animals have all four types of teeth. Incisors are used to shear or cut through food; canines are used to grip food and for defence; premolars are the transitional teeth between canines and molars and have the initial grinding function during transfer of food to the back of the mouth; molars are the principal grinding teeth that mechanically break down the food during chewing prior to swallowing.

As teeth have the primary function of securing nutrition and assisting digestion, it is not surprising that the number and structure of teeth vary greatly with species. Some animals, such as sharks, have multiple sets of teeth over the course of their lifetime whereas others, such as mammals, have only two sets - deciduous and permanent. In many animals, like **carnivores**, once fully erupted the permanent teeth stop

growing and, indeed, gradually wear down over time. In other animals, especially herbivores like **rodents**, lagomorphs and equines, the permanent teeth continue to grow, with the rate of growth ideally matching the rate of wear due to diet. The dentition of any animal can be described using a dental formula, which gives details of the number of teeth in one half of the maxilla (upper jaw) over the number of teeth in one half of the mandible (lower jaw). For example a dental formula of 3.1.2.3/3.1.2.3 would mean that the animal in question has a total of six incisors, two canines, four premolars and six molars in the top jaw and the same in the bottom jaw.

In general, teeth are comprised of:

- a pulp cavity, containing blood vessels, nerves and soft connective tissue;
- dentine, a mineralized connective tissue between the pulpy cavity and the outer layers of the tooth;
- cementum, a bony substance made up of collagen and hydroxyapatite that covers the root of the tooth;
- enamel, a highly mineralized substance of hydroxyapatite and enamelin covering the outer exposed surface of the tooth.

In some species, such as **horses** and young **cattle**, the age of the animal can be estimated by either the number of permanent teeth that have erupted or their state of wear. Also in some species, extended canine teeth are used during fighting with **conspecifics** or during defence from predators. In **pigs**, these teeth may be removed soon after birth to prevent the piglets damaging each other or the sow's udder.

Training of animals

Animal training describes the process involved in ensuring that learning comes about in a predictable way within an animal in response to human intervention. Therefore, training involves not only the application of learning theory (**see: Conditioning - types of**) but also interspecific **communication**, either of which may affect the **welfare** of the trainee. For example, in relation to the application of learning theory, the excessive, unnecessary or inappropriate use of **punishment** may compromise welfare, through both physical and non-physical means; poor training technique resulting in the non-contingent application of **aversives** may result in **learned helplessness** or chronic **anxiety**.

However, even training methods that focus on the delivery of positive **reinforcement** may give rise to problems. For example, the frequent use of continuous schedules of reinforcement may give rise to the expectation within the trainee of a high rate of reinforcement that, if not met, might lead to **frustration** and **distress**. Failure to appreciate how context-specific learning may initially be can lead to unrealistic expectation of the animal's behaviour and the inappropriate application of aversives as a consequence; for example, a **dog** may learn a response in the training hall, but not generalize to the wider environment. Understanding the principles of **stimulus** control in this regard is crucial. Thus a dog may respond to a command issued by one person but not by another for the same reason (and not due to stubbornness or a **preference** for one individual over another), i.e. because the command is recognized in one context due to its similarity to the one used in the training context, but not in the other due to its difference. When 'instructing' an animal, it is important to appreciate that it is really a request that is being made, which the animal may ignore deliberately, perhaps because of other, competing **motivations**, or inadvertently because it does not recognize the request due to poor communication. In either case the onus is on the trainer to remedy the situation through appropriate means, which will differ according to the cause.

Although many 'new age' or 'ethological' training methods for animals have been developed that are claimed to be more humane, these generally involve the application and communication of simple and traditional learning principles in a particular way, for example through the use of more ethologically relevant cues. Because animals differ in how they respond to others and to reinforcement, the most sound training package is one that uses a flexible approach and is based on establishing the application of declarative **knowledge** relating to animal training rather than one focused on **procedural knowledge**, as is often the case in the 'new age' training packages.

In order to train an animal efficiently, the author recognizes ten considerations for the trainer, all of which have potential welfare implications:

- Is the animal physically and psychologically fit for training?

- What is the end goal and how is this defined?
- How is the **attention** of the animal to be obtained in order to establish communication with it?
- What is going to be the cue for the behaviour (i.e. the stimulus that indicates that a reinforcement schedule is in operation)?
- What is being done to encourage the animal to make the decision the trainer desires?
- What is being done to reassure the animal that this decision is a good choice?
- For efficient training it is also worth considering which aspect of the behaviour is to be reinforced (e.g. its latency, duration, etc.).
- What is the most appropriate training set-up, e.g. differential reinforcement of a spontaneous or lured behaviour (**see: Shaping (operant)**)?
- What degree of generalization or discrimination is required in the end so that training can be arranged accordingly?
- It is important to determine how the training can be objectively assessed and monitored so that modifications can be made on a rational basis.

It has been claimed that punishment is associated with a higher risk of **problem behaviour** (Hiby *et al.*, 2004), but it is difficult to establish whether the use of punishment is causative or the consequence of misbehaviour. Any training method can be misapplied or abused and give rise to welfare problems, but certain methods of training attract particular criticism, for example the use of electronic training ('shock') **collars**. While opponents claim these devices are inevitably cruel - often focusing on their use as a form of punishment - proponents point out that they can be used as part of an integrated training system (whereby the current is used to interrupt ongoing behaviour rather than to punish it, to notify the animal that an alternative form of positive reinforcement is available - consideration three, above). Used in this way, the

P.612

device would be expected to cause minimal **suffering** in the short term and its success, particularly in establishing a reliable recall, is to the long-term benefit of the animal, for example by allowing it greater freedom.

Clearly, these debates are complex and the ethical arguments articulated are not always consistent. Owners are generally more opposed to the use of electric current for the control of behaviour than to other forms of aversives - for example, a spray of citronella to control barking; however, if either method is effective, then it must be acting as a form of punishment and it is perhaps anthropomorphic (**see: Anthropomorphism**) to suggest that an electric current is necessarily more aversive than a strong odour to an animal with a long coat and highly developed sense of smell. Further research is undoubtedly required to answer such questions.

Other causes for concern, in relation to the welfare of animals undergoing training, include the general lack of regulation of this field as a profession and the difficulty faced by the average animal owner in establishing the quality or value of a given trainer.

Transgenics

Transgenics are animals that have a gene, or genes, from another animal, usually of a different species, incorporated into their **genome** in such a way that the transgene is incorporated into the germ line and so will be inherited. However, it is often applied to any animal that has had its genome modified in some way. This can be by either: (i) the addition of a

specific gene, or genes; (ii) the addition of either a specific sequence of DNA (called a 'knock-in', say with a faulty gene to study its function) or of several copies of a gene, for example **growth hormone (GH)** for increased agricultural productivity; or (iii) the deletion of part of an animal's normal DNA ('knock-out').

These procedures are carried out on recently fertilized ova by micro-injection techniques. Such animals are used in research to better understand normal and **abnormal** development, as well as for the identification of specific genes and the roles that genes play in **disease**, such as causation, susceptibility and resistance.

Transitional phase

The term transitional phase in relation to behavioural development refers to a **sensitive phase** of development between the **neonatal period/phase** and **socialization phase**, during which there is rapid development and adaptation of the external sensory organs to the prevailing environmental circumstances.

(DSM)

Translocation

Translocation is the intentional capture and transfer of **wild animals** or populations from one part of their historic range to another (see also: **Reintroduction**). Translocations are used to establish, re-establish or augment a wild population to increase the viability of a species or to supplement **game animal** populations. They are also used as a control measure to remove nuisance animals from areas where they are causing damage, and thus alleviate human-animal conflict. Most translocation research has focused on mammals and birds, but translocations have also been conducted with fish, **amphibians** and invertebrates. Though translocation has become an increasingly popular **conservation** tool, most translocations fail to produce sustainable populations and involve risks such as **disease** transmission. This has led to an increased interest in determining the factors that influence the success of translocations and to design methodology to minimize transmission of disease.

Post-translocation **mortality** is highest in the first days to weeks following release, as animals make settlement decisions and modify the release-site habitat to accommodate their needs. Problems associated with this initial establishment phase include: (i) post-release dispersal (i.e. long-distance movement away from the release site); (ii) **predation**; (iii) **stress** response to the novel environment; (iv) difficulty finding food; and (v) **competition** for **resources** (e.g. **territory**) with **conspecifics** - either residents or fellow releasees.

Among the proposed explanations for the high mortality during the establishment phase, post-release dispersal and predation are thought to be important factors. Immediate rejection of a release site indicated by post-release dispersal has been documented in many species. In some cases, translocated animals travel all the way back to their natal habitat (i.e. 'homing'). Long-distance movement and, for many species, the required habitat modifications (e.g. digging burrows) leave translocated animals particularly vulnerable to predation immediately after release.

Post-release **dispersal and habitat selection** may initially be high because animals: are site faithful; are not familiar with the physical characteristics of the release site or with the individuals with whom they were released; or are at a disadvantage when competing for resources with residents. Biologists studying translocations are beginning to understand these problems and modify translocation methodology to address these issues. For example, to dampen post-release dispersal and decrease stress, biologists have used 'soft' release techniques, where the animals are provided with some form of support during the release (e.g. a period of time in an enclosure on the release site and/or supplemental food being provided after release). Compared with 'hard' release (e.g. direct release without an acclimation period), soft releases are generally thought to enhance the likelihood of translocation success, via increasing site fidelity and post-release survival. However, results of the few studies that have directly addressed this question are mixed, possibly because other factors that influence translocation success (e.g. predators) outweighed the effects of this technique.

Whether soft release methods are beneficial may also depend on the social system of the species. For example, in wild **rabbits**, soft release enhances survival for females but not for males. European wild rabbits live in highly stable **social groups** composed of a few males that defend a group of

related females from unfamiliar males. Because translocated rabbits were trapped and held with unfamiliar individuals in

their acclimation cage, soft release may have increased rather than decreased stress of translocation for males, thus rendering this procedure detrimental.

Newly translocated animals may also leave the release site because there are no resident conspecifics, which may indicate that the habitat is unsuitable. For example, black **rhinoceros** move less during the first 5 days after release if cues that signify conspecific presence (i.e. dung) are broadcast at the release site.

Alternatively or in addition, founder group composition may influence translocation success. Group size, age and sex class ratios, and familiarity between founder group members have all been shown to affect survival post-release. While there is a positive relationship between the size of the founder group and survival across taxa, suggested age and sex class ratios may vary by **mating system**. For example, black **bear** are polygynous. Males have large **home ranges** that overlap with as many as nine females. Thus, suggested translocation schedules include a release of males prior to release of females to allow males time to establish breeding territories into which females can settle.

Composing founder groups of intact social groups has been shown to have a significant influence on translocation success. For black-tailed prairie dogs, founder groups composed of intact families were more successful in terms of post-release survival, reproductive success (see Fig. T.2) and population viability. Maintaining family unity appeared to reduce the effects of successful predation on prairie dogs and dampen post-release dispersal.

Thus, any species dependent upon social interactions for survival and **reproduction** may benefit substantially from the maintenance of social groups during translocations. Species for which social interactions enhance individual **fitness** would be especially likely to benefit from the maintenance of social groups during translocation. Those species include species with kin-selected behaviours (e.g. Belding ground squirrels' alarm calls), those that rely on **reciprocity** (e.g. **allogrooming**; helping at a communal nest) and those that receive direct benefits from relationships with group members (e.g. coalition formation, social foraging, sexually selected cooperation, **social learning**, enhancement of immune function and reduced disease transmission and stress).

Fig. T.2. Differential survival rates of intact versus incomplete social groups.

Predation is a significant impediment to translocation success. The effects of predation are especially prevalent during the establishment phase. Most attempts to minimize predation on newly translocated animals have involved monitoring of release sites post-release and predator removal (see also: **Predator control**). In many cases, novel predators are one of the primary selective forces that caused the initial decline of the target species. In these situations, it is crucial that the novel

predators are removed from the release site prior to translocation and/or releasees are trained to avoid the novel predators.

Transmissible disease

Diseases caused by pathogens that are passed on from one animal to another are transmissible. The transmitting animal may or may not be of the same species. Transmission can occur through contact with excretions (faeces, **urine**) and secretions (venereal, saliva), by inhalation (droplets in the breath) and by inanimate objects that have been contaminated (fomites). A contagious disease is, strictly speaking, one that is spread by direct contact between animals, while an infectious disease is one that may or may not be easily transmissible. When animals are immunosuppressed infection may occur more easily.

(DBM)

Transport

Animals are transported for a number of reasons. It is unfortunately the case that the reason for transport, the type of animal and its inherent value will potentially affect the amount of care accorded to the process and the likelihood that the animal's **welfare** might be compromised. For example, **pet** animals, **breeding** stock and racehorses are likely to be handled carefully and their welfare will generally be good. In contrast, the trade in animals transported to **slaughter** is subject to commercial pressures that may lead to them being handled less carefully. Very young animals, such as small calves, may also be particularly vulnerable by virtue of their physiological immaturity.

Modes of transport

The majority of animals are transported by road. Air travel is used for particularly valuable animals such as pets, racehorses and breeding stock, but also increasingly for day-old chicks. Rail travel has decreased in importance from its early historical pre-eminence, with the improvement of roads. Animals such as large **zoo** species, racehorses and **horses** used for other

recreational purposes travel in relatively sophisticated vehicles, often in individual compartments. **Cats** and **dogs** are often transported in individual crates or containers. Animals destined for slaughter usually travel in simple vehicles, often multi-decked, in which the decks are subdivided into pens holding a number of individuals. The number could range from as few as four or five in the case of adult **cattle** to perhaps 30 in the case of **sheep**. Transport by sea is used for a relatively small proportion of journeys, mostly for exported animals. Sheep are exported from Australia to the Middle East in ships that hold up to 100,000 animals. The number of animals transported is therefore significant, although the number of journeys is small.

Poultry such as broilers, **turkeys** and hens are transported commercially in loose plastic crates or in the drawers of 'modules' (see Fig. T.3). These are metal frames into which the plastic drawers slide. Each crate or module drawer might hold from 15 to 25 birds, depending on live weight. An entire module might hold 12 drawers and therefore 300 birds. The modules can be handled and lifted on to a flat-bed lorry using a forklift truck. A loaded lorry might carry 5000-6000 birds.

Because ventilation is passive, and is impeded by the close stacking of the crates or modules, close environmental control is very difficult. This may lead to very high temperatures developing, particularly in the centre of the load, with the danger of the birds suffering hyperthermia. A 5°C increase over ambient temperature is common, and temperatures of $\geq 30^{\circ}\text{C}$ in the centre of the load have been recorded. By contrast, the birds in the outermost containers may suffer hypothermia if the weather is cold, especially if they become wet so that their **feathers** lose their insulation properties. To reduce this possibility many poultry transporters are fitted with adjustable side curtains that protect the otherwise exposed birds. Unfortunately their use may make the situation of the innermost birds on the lorry more difficult by further reducing air circulation.

So-called day-old chicks for stocking of commercial growing units are transported from the hatcheries in specially designed cardboard boxes. The chicks are in fact usually 1-3 days old when transported and are reliant on the contents of their yolk sac for energy and water from hatching until they reach the rearing units. Chicks of modern broiler **genotypes** have higher metabolic rates than traditional genotypes, and use up these reserves more quickly. It is therefore essential to avoid delays in placement, and to ensure that metabolic and thermoregulatory demands on the chick are controlled. Chicks must be kept warm, so temperature and humidity control of their microenvironment is very important.

Fig. T.3. A module containing 12 drawers used in the commercial transport of poultry.

Fish are sometimes transported live, particularly ornamental fish or for restocking. The main factor in determining **fish welfare** seems to be water quality. To this end it is important to ensure sufficient volumes of water to prevent the build-up of dangerous waste products such as ammonia, and to have adequate oxygenation.

Major factors affecting welfare

Welfare during transport is a function of the length of the journey and the conditions prevailing. The time taken is often more important than the distance travelled (**see: Journey times**). However, short journeys under poor conditions may be worse than long journeys under good conditions. Legislation and **codes of practice** relating to the protection of the welfare of animals during commercial transport therefore often prescribe maximum journey times and the various factors that influence these conditions. These include rest, feed and watering intervals, minimum **space** allowances on the vehicle, how

animals are penned, ventilation requirements as they affect the microclimate around the animals, and other aspects of vehicle design. For example, current European Union Directives specify that, using appropriate vehicles, adult sheep and cattle may be transported for a total of 29 h. After the first 14 h the vehicle must stop for 1 h and the animals must be offered liquid and, if necessary, be fed. After this they may be transported for a further 14 h. Journeys may be prolonged for a further 2 h (over the 29 h) in exceptional circumstances and if this is to the benefit of the animals. After the whole journey the animals must be rested for 24 h before any further transport. Legislation also often prescribes the level of experience or training required by drivers and the records of each journey that must be kept. Records enable the monitoring of compliance with the law.

Individual journeys for animals for slaughter are often part of a wider marketing system where the animals also pass through one or more live auction markets (**see: Market**). With these relatively complex systems it is often difficult to ensure that the animal's welfare through the whole process is being adequately protected, as each stage in the chain is treated separately rather than being considered as part of the wider whole. Animals may therefore go for very long periods without adequate rest or access to food and water. Additionally, animals that pass through live auction markets suffer a greater amount of bruising. This is probably both because they are necessarily handled more, so there is a greater chance of falls, slips and contact with sharp projections, and because handlers in some livestock markets may be less careful than they should be.

An important part of the transport process is the preparation and loading of the animals. Preparation includes making up groups of animals and, if appropriate, ensuring a

P.615

period of food deprivation before transport. **Pigs** do not travel well on full stomachs and, in animals destined for slaughter, a balance needs to be struck between prevention of unnecessary **hunger** and the requirements for good hygiene at slaughter. Full guts make evisceration more difficult, and the consequences of accidental cutting or tearing of the gut wall more serious.

Loading and unloading of the larger animals can be a particularly stressful procedure. The use of level loading docks and hydraulic tail lifts, rather than ramps, will reduce **stress** and the chances of physical **injury**. For most animals the provision of appropriate bedding on the vehicle is important to cushion them from the effects of vibration and to soak up **urine** and **faeces**. Because of this, legislation often prescribes its provision unless alternative arrangements are in place to deal with waste material. For example, pigs are sometimes transported on perforated **floors**.

Time spent in transport

Journey times can range very widely - from an hour or two in the case of breeding animals sent by air, or meat animals sent to slaughter at local abattoirs, to several days for animals exported by road or sea for slaughter or further fattening.

Journeys involving sea crossings can be of particular concern from the point of view of animal welfare, partly because they are often long, and partly because conditions at sea tend to be inherently poorer.

Stresses of transport and animals' responses to them

Even when carried out with care, the transport of animals is likely to be stressful. The stresses involve removal from their home environment and close **confinement** in unfamiliar surroundings and exposure to vibration and noise, unfamiliar animals and extremes of temperature. Animals often suffer the breakdown of social groupings, which may lead to stress or even fighting, and deprivation of food and water (**see: Social stress**). Falls may result in trauma such as bruising. The microclimate in the interior of vehicles may be poor, with the build-up of noxious gases such as ammonia. The commercial transport of poultry is of particular concern in this regard. Too high stocking densities can compromise the ability of animals to thermoregulate, and especially to lose heat, at high ambient temperatures (**see: Stocking density; Thermoregulation**).

Animals react to the stresses of transport in various ways. Psychological stress leads to increases in **heart rate** and the release into the blood of hormones such as **catecholamines** (adrenaline/**epinephrine**) and **corticosteroids** (cortisol, corticosterone), and physical stress to increased circulating levels of enzymes such as creatine kinase (CK). Pigs can become travel-sick and show elevated concentrations of the hormone vasopressin. Dehydration is reflected in increased plasma osmolality, and prolonged fasting in increases in non-esterified fatty acids (NEFA) and ketone bodies. Prolonged transport often leads to significant loss of live weight, partly because of the enforced period of fasting but also as a direct consequence of the stresses associated with the journey. Animals that usually remain standing during even prolonged

transport, such as adult cattle, probably suffer from greater fatigue than animals that will lie down if given suitable conditions, such as pigs.

The transport of many **wild animals**, for example to import them into zoos and game parks or relocate them to new areas or reserves, is particularly difficult because of the severe reactions they often show to the process. For these animals it may be essential to tranquillize them immediately after capture and before loading on to the vehicle, to prevent them dying. Even then, some will show 'capture myopathy'. Tranquillizers are unacceptable for meat animals because of the potential danger to human health of drug residues.

It is important that transported animals are fit to travel. Unfit animals include those that are heavily pregnant or have recently given birth, newborn mammals and animals that are lame, injured or severely ill.

Temperature, humidity and ventilation

Pigs and poultry are particularly sensitive to high temperature and humidity during transport. This reflects their relatively poor ability to thermoregulate under the confined conditions of transport. Normally, pigs rely on evaporative heat loss facilitated by wallowing. This is obviously impossible within the confines of a normal transport vehicle. Poultry lose heat by spreading their wings, again impossible in the confines of a crate, or by panting so that water is evaporated from the respiratory tract. The value of this is obviously reduced or nullified at the high relative humidity that tends to develop under these conditions. Ventilation tends to be compromised at higher stocking densities and therefore, when high ambient temperatures are expected, many hauliers will increase the space allowance per animal.

It is, however, important to be aware of the dangers of high temperatures to stock and in summer to travel whenever possible during the cooler parts of the day and to avoid stopping unnecessarily, so that ventilation is maintained. In animals exported over long distances the range of environmental temperature experienced may be large, with both very low and high temperature being potentially stressful. In northern latitudes where very low temperatures can occur, it may be necessary to have insulated vehicles. Low temperatures are also a danger to poikilothermic animals such as **reptiles**. In this case heated containers are essential.

Space allowances

For the commercial transport of slaughter animals hauliers will tend to use the maximum stocking densities possible, as this will reduce the unit cost of transport. High stocking densities make it more difficult for individuals to maintain their balance during changes in velocity of the vehicle. The idea that at high stocking densities standing animals support one another seems to be unfounded, based on observations of the number of falls occurring given different amounts of space. Generally, animals should be given at least enough space to lie down if they wish. Under these conditions, provided that bedding is adequate to ensure comfort, pigs and sheep will often lie down during longer journeys. Adult cattle may not do so if transported as **groups**, and this may make them more prone to fatigue after long journeys.

Provision of food and water

During commercial transport and the associated **handling**, many animals may become hungry and thirsty because of the

P.616

impracticality of supplying food and water during the journey. This highlights the need to ensure that animals are adequately fed, watered and rested before loading. However, it is generally considered unwise to feed pigs right up to this time, and a minimum period of 4 h from the time of last access to feed and loading has been recommended. This will reduce the chances of the animals suffering travel sickness. The mortality rate during transport is also reduced. The reason for this is unclear, but may be because a full stomach can impair venous return, leading to circulatory insufficiency. Pigs appear to become quickly dehydrated during transport. To alleviate this, European Union legislation requires that pigs have continuous *ad libitum* access to drinking water in journeys longer than 8 h. Experience, however, shows that the amount of water actually consumed is relatively small compared with the animals' normal intake, but for reasons that remain obscure.

Ruminants may be more resilient than non-ruminants to the effects of food and water deprivation, because the rumen acts as a store of nutrients and water. However, long periods without food undoubtedly disrupt ruminal function and this may itself be distressing to the animal. Horses are particularly susceptible to dehydration and should therefore be offered frequent access to water.

Effects of transport of animals for slaughter on carcass and meat quality

Transported animals can die in transit, especially under adverse conditions. In Europe and North America **mortality** rates for slaughter pigs average about 0.1%, but can be much higher in very hot weather or in genotypes that are stress susceptible. Mortality rates for poultry are at least double this. Transport often results in bruising, which, as well as being a welfare issue, reduces carcass value. The fatigue and stress associated with long journeys can deplete muscle glycogen stores. If severe, this can lead to the production of so-called dark firm dry (**DFD**) **meat**, characterized by a reduced extent of post-mortem acidification and a high ultimate pH value. As well as its appearance being unattractive to consumers, and having poor eating quality characteristics, because of the high pH, DFD meat spoils rapidly and thus has a relatively short shelf life.

Effects of transport on disease control

Disease can compromise animal welfare as it is likely that diseased animals will suffer **pain** or **distress**. Transport has implications for disease control because it can lead to the wide geographical spread of disease between animal populations. Since exposure to stress may reduce the function of an animal's **immune system**, transport can also affect the susceptibility of individuals to infection. This effect is exemplified by the disease known as 'shipping fever', usually caused by the bacterium *Pasteurella*, which is a problem in young calves transported long distances to **feedlots**, particularly in North America.

Recovery from transport

Animals may need considerable time to recover after long transport. This will be especially so if they are dehydrated and, in the case of ruminants, have been deprived of food for a long time such that ruminal function is disrupted. Recovery times are poorly defined but are probably at least 1-2 days, even under ideal conditions.

Improving the welfare of animals during transport

In the future it is likely that there will be pressure for the commercial transport of animals to come under greater control, with more stringent monitoring of compliance with legislation. There are also likely to be greater restrictions on the maximum length of journeys before animals must be rested, and increases in the length of these rest periods. The design of livestock transport vehicles will probably improve, with greater use of air suspension systems to reduce vibration and noise, monitoring of the microclimate within the pens and automatic control of ventilation to maintain optimum temperature and humidity. To reduce the dangers of overheating, mechanical ventilation systems are likely to replace current passive systems. Loading and unloading systems are likely to be improved, with the replacement of ramps by hydraulic lift systems. Much greater attention to the adequate training and accreditation of vehicle drivers will also ensure that the people primarily responsible for the welfare of the animals during transport have adequate knowledge to fulfil this role.

Trophic cascade

A trophic cascade describes the change within an ecosystem that arises when one level of a food web increases in success and so reduces the density of the next level down, which in turn affects the third tier. Thus a shift upwards in the success of a large top predator may result in a reduction in the level of their prey in the ecosystem, which might be a **mesopredator**. This may, in turn, result in an increase in the numbers of the normal prey of the mesopredator, which might be herbivores, and increase competition within them for **grazing**.

Turkey

Turkey is the common name for a large gallinaceous bird with a fan-shaped tail and a bare, wattled head, which has become widely domesticated for food. The name is derived from its distinctive 'turk-turk' call. Turkeys show sexual dimorphism, with the male being approximately 1.5 times larger than the female. Other differences between the sexes can easily be identified during sexual displaying: the male's head region will change colour from pink to a mix of blue, red and purple, while the female's head region remains pink.

P.617

Natural habitat, feeding and maintenance behaviour

Wild turkeys (*Meleagris gallopavo*) range over North America from southern Mexico to the north-eastern USA. Their habitat is diverse, ranging from low, moist and hot coastal plains to swamps and mountains. *M. gallopavo* includes five subspecies of wild turkeys and all domestic varieties. Recognized subspecies are the Mexican turkey (*M. g. gallopavo*) of central Mexico, Merriam's turkey (*M. g. merriami*) in the mountainous areas of south-western USA and northern Mexico, the Rio Grande turkey (*M. g. intermedia*) of Texas and north-eastern Mexico, the Florida turkey (*M. g. osceola*) and the Eastern turkey (*M. g. silvestris*), ranging from Texas and Nebraska to the Atlantic coast and the north-eastern USA.

Wild turkeys are omnivorous, with their diet consisting of a variety of berries, seeds, leaves, grasses, insects, crustaceans and small **reptiles**. Turkeys do not show any specialized adaptations of feeding - they exhibit the basic avian feeding pattern. It is not necessary for the bird to raise its head to swallow food, which suggests that swallowing is an active process. Drinking is accomplished differently from feeding, as the head is raised, the beak is extended upward and the beak is closed several times in rapid succession. This suggests that there is a degree of active swallowing in addition to the flow by gravity to the oesophagus.

Scratching behaviour is an important component of foraging for food, and gallinaceous birds scratch with one foot while standing on the other. Wild turkeys extend the foot forward and scratch backward and outward in a sweeping motion to form an inverted 'V' pattern on the ground. In domestic turkeys scratching behaviour is rarely seen on the range or in the litter provided in houses. The reduction in scratching in domestic turkeys may reflect reduced **motivation** associated with genetic change during **domestication**. Alternatively, turkeys may still be motivated to scratch but are prevented from doing so by physical constraints or inappropriate environmental provision (Hale *et al.*, 1969).

Newly hatched poults (young birds) will peck indiscriminately at objects that contrast with the background. This response leads to the poults pecking at feed and images in the water, and so initiates feeding behaviour. **Social facilitation** of this behaviour is provided by other poults. If novel objects are presented to the birds, curiosity pecking is initiated, and there appears to be little evidence of **neophobia** as compared with **chickens**. The digestive tract of the turkey is similar to that of other poultry species. In turkeys, along with many species of galliform, **preening** and **dust bathing** are common compared with water bathing. Dust bathing is influenced by litter condition; it is facilitated when dry, friable litter is available. Preening is observed throughout the day, but especially just after lights on and just before lights off. Turkeys can develop problems of **feather pecking** and **cannibalism** in captivity.

Social behaviour

Many interactions occur between individuals and **groups** of turkeys. **Social behaviour** in turkeys includes aggressive, submissive and sexually related activities, parent-offspring interactions, synchronized behaviour and competitive activity.

The social stratification of a population of turkeys is highly developed in the wild turkey (**see: Hierarchy**). The status of each individual is determined by the end of its first year, and usually remains fixed for life. Males are usually forced into two contests around 6 or 7 months of age when they leave the brood flock: one establishes his position within his group of

siblings and the other determines the status of his sibling group with respect to other groups. Fighting consists of pecking at the head and neck. The strongest fighter in the group becomes the dominant bird, and the order of rank is established among siblings and seldom changes as long as the dominant bird lives.

Females in the group also establish social dominance through contests. When males leave the brood flock, females fight for individual rank among themselves but, unlike the males, there is not fighting among flocks (Watts and Stokes, 1971).

Wild turkeys are gregarious except at **breeding** time, and are polygamous. They are non-migratory, even though they are good fliers. Their breeding behaviour is based on the **lek**. The female builds the ground nest and will lay 8 to 15 eggs per clutch, which she will brood. At hatching the poults weigh 2 ounces (55 g) and have yellow down with usually brown markings. Within 10-12 days the first flight **feathers** begin to show and, by the end of the first month, all the yellow down has been replaced with plumage.

Domestication

Domestication first occurred in the seed-planting **culture** of the Aztec Indians of Mexico. Domesticated turkeys were then brought from Mexico to Europe through Spain during the 16th century, and several European varieties have since been developed.

Present farming practices

The turkey cycle

Fertility under natural mating conditions in commercial flocks does not have a high success rate, possibly because of the natural lek-based mating system. Genetic selection for broad-breasted strains now means that commercial males may be up to three times heavier than the females to which they are mated, and **artificial insemination** is therefore usually necessary (Hocking, 1993).

The average female breeding turkey is kept for over 1 year and does not enter lay until 28-32 weeks. It is necessary to rear breeding birds under high light intensities to induce them to lay. Breeding turkeys typically produce between 45 and 60 live young per year. The incubation period for a turkey egg is approximately 28 days. Once the poults are hatched they are moved to a brooder unit, when birds are placed within surrounds where feeders and drinkers are available. The purpose of the surround is to condition the poults to locate drinkers and feeders, and to ensure the birds are maintained at the correct temperature. Day-old poults are initially raised at 35°C, and this temperature is usually reduced by 1°C every 3 days until 21°C is reached. At 6 weeks of age the surrounds are removed and the poults are either given access to the whole shed or to a range, or are moved to another farm, called 'brood and move'. Around 18 weeks female turkeys reared for meat purposes are depopulated (slaughtered) and the whole carcass is typically used. Around 21-25 weeks male turkeys used for meat purposes are

P.618

depopulated, and the meat from these birds is usually cut into portions. Birds of both sexes reared for meat are called growers.

Growing and breeding turkeys reared in the UK are usually given *ad libitum* feed and water, although breeding birds receive diets with lower protein levels and grow more slowly than grower birds. Growers typically have three or four changes in diet, whereas breeder birds will have more changes in diet. For the first 8 weeks turkeys are fed turkey starter crumb feed, which is high in protein, and are then fed on turkey grower feed from around 8-12 weeks, and from 12 weeks to depopulation the birds are reared on turkey finisher feed, which is high in fibre and fat. In some countries no animal substance is permitted in turkey feed, so the main source of protein is from soybean.

Housing of meat turkeys

Commercially reared turkeys are grown in a variety of **housing**, ranging from conventional (enclosed, controlled environment) sheds to **free-range** conditions. Another popular method of rearing turkeys is in a pole barn system. This allows access to natural daylight, but there is little ventilation or temperature control in these systems. Free-range systems provide the birds with access to an outside area and subject them to natural light conditions. The majority of turkeys are reared in single-sex flocks, but smaller flocks may be mixed sex.

Welfare concerns

Due to the variety of turkey-rearing systems birds may be kept in many different environments, so some of the **welfare** issues raised below will not be relevant to all birds. For example, there is a huge range of flock sizes of commercially reared turkeys, from a few hundred in pole range or range systems to tens of thousands in conventional houses. Different systems have various minimum available **floor** area guidelines, with conventional houses having a minimum of 260 cm²/kg and enclosed range areas with 10 m²/kg.

Turkeys are vaccinated against numerous **diseases**, administered to the birds through a variety of methods. For example, turkey rhinotracheitis live vaccine is sprayed on to the turkeys when they are 1 day old; avian encephalomyelitis live vaccine is administered to the birds in their drinking water; and pasteurella, Newcastle disease and Paramyxovirus type 3 vaccines are all administered via intramuscular injection.

Lighting used in conventional turkey houses is either incandescent or fluorescent bulbs. Turkeys reared in conventional houses are typically kept in light intensities between 1 and 10 lux as a control strategy to reduce feather pecking and cannibalism. Intensities as low as 1 lux can cause buphthalmus (enlarged eye), and increased intraocular pressure and enlarged **adrenal glands** (Siopes *et al.*, 1984). Turkeys will preferentially select high light intensities while spending very little time in very low-light environments (Sherwin, 1998; Barber *et al.*, 2002).

Another way the industry controls feather pecking is by **beak trimming** of birds kept in open housing where the light environment cannot be controlled. These include breeders, as they require light to stimulate lay, and turkeys reared in pole barns and extensive systems, where they are subjected to high light intensities. This practice is also known as debeaking, or partial beak amputation, and most UK turkey companies will beak trim the birds before 21 days of age, and will remove up to one-third of the upper mandible. Three main methods are used to beak trim birds: electronic trimming (bio-beaking), cold cutting (with secateurs) and hot cutting (with a cautery iron). There is no evidence that beak trimming causes chronic **pain** in turkeys trimmed up to 21 days old (Grigor *et al.*, 1995). Breeding birds may be beak trimmed twice, as they are reared for over a year and it is possible that the beak may grow back.

Some turkey producers toe clip birds, either removing one, two or three toes at the junction of the first and second digit, or at the nail end. This prevents damage from scratches on the skin, which can downgrade the carcass. This may occur if the flock crowds into a small area such as a corner when startled. Back scratches may also occur during catching and transportation to the killing plant.

Males have a secondary sexual organ, the snood, which is at the base on the beak. The snood can be pulled during male fights and can be pecked by females in a mixed flock. This can cause damage and provide an area for disease entry. Some turkey producers remove the snood at 1 day old to prevent this damage from occurring. The organ is well innervated, but there is no information as to whether the snood removal process is painful or whether it leads to chronic pain.

It is important to keep the litter in a good, friable condition. Certain litter conditions can cause the development of breast blisters, which may cause discomfort to the birds and also downgrades the carcasses. Contact with ammonia or other noxious materials, including faecal enzymes in the litter, could result in breast blisters. The length of the **photoperiod** is also known to increase the chance of birds developing breast blisters. The longer the dark period the greater the chances of breast blister development, possibly because birds lie down for longer without moving.

Leg weakness can be a welfare problem for commercially reared turkeys (**see: Bone strength**). Genetic predisposition, nutrition, infection, mycotoxins, medication, husbandry practices and interactions between them have all been associated with leg weakness. Large strains usually show higher incidences of leg disorders than lighter stocks. This may be due either to weight effects or a consequence of a genetic correlation between body weight and defective bone growth (Hocking, 1993).

Sudden changes in the environment, such as the presence of a predator or rapid change in the light environment of the turkey house, can panic the birds, which may cause them to trample and damage other birds. Turkeys will 'pile up' against walls or in corners if startled, which can lead to smothering and **death**.

Twitch

Twitches are used to constrict the skin, usually of the upper lip of **horses**, in a bid to restrain them. Such nose twitches are simple and relatively safe for both horse and operator. For brief, mildly invasive procedures, they may help to immobilize the horse. That said, some experienced horses respond aversively to the mere sight of the twitch. This response strongly suggests that **pain** is involved. Twitch designs vary from a simple loop of rope attached to a metal ring that is twisted to tighten the rope, through to the so-called humane twitch (a pair of metal pliers, which, in the hands of a novice, may cause less tissue damage than a homemade twitch).

Pressure is a function of area (e.g. pounds per square inch or kPa), so with any piece of equipment used on horses, the broader the area that touches the animal the less discomfort it causes. Thus broader areas are covered by tack, such as the girth, to which we expect the horse to habituate. In contrast, other sources of pressure are intended to cause a response, so **sensitization**, rather than **habituation**, is required. The narrower the structure in touch with the horse, the greater the stimulation and potential for pain, but so too the likelihood of permanent damage. For this reason soft, thick rope is generally favoured in twitch designs. Because horses wearing a twitch may evade the pain by moving the head rapidly from side to side, twitches with plastic handles are generally the safest for personnel. The constriction around the nose should be loosened every 15 min or so to maintain cellular perfusion distal to it. In many cases, the effectiveness of the twitch tends to wane after this period, possibly because of neurotransmitter depletion at the level of synapses in the **opioid** pathways.

A rope gag (also known as war bridle) involves a cord passed under the upper lip and over the poll, before being threaded through a loop at the side of the face to form a running noose. It has an action similar to the twitch when pulled tight.

Variations on this design, including the use of metal chains rather than cord, appear in the equestrian literature (lip chain). A piece of rubber tubing slipped over the portion of the rope that presses on the underpart of the lip reduces the risk of **injury** without appearing to reduce the effectiveness of the device. Although they are vehicles for escalated force, these devices are sometimes advocated for problems in the ridden horse. The inherent dangers with this sort of equipment are considerable. Rather than force, better timing and consistency is preferable to severe equipment that, through habituation, creates self-perpetuating reliance on force.

Among veterinary professionals, physical **restraint** of horses with twitches during painful procedures is often possible, but rarely preferable, to chemical restraint. In a cost-benefit analysis (**see: Utilitarianism**), the use of the twitch seems legitimate, if the alternative is a brutal struggle or an opportunity for the horse to practise a hazardous flight response. Fundamentally, the use of force in a fearful animal can escalate the aversiveness of the interaction and is ultimately likely to compromise the horse-human bond, making the horse less compliant for future procedures.

In very difficult horses, the ear is sometimes grasped briefly to control the horse while a twitch is put on the upper lip. However, this technique should be avoided because it is far more likely to create head-shyness in the long term than compliance in the short term. Twitching the ear is not appropriate because it may make the animal head-shy, scar the skin or paralyse the ear.

At best the twitch can be seen as a variant of acupuncture (Lagerweij *et al.*, 1984). Its effectiveness varies between individual horses, its application increases plasma concentrations of **beta-endorphin** and its action can be blocked by the opioid antagonist naloxone. Even though the twitch may work through the mediation of beta-endorphins, there is little doubt that it works because it involves pain (Webster, 1994). Current recommendations suggest that twitching a horse's lip should be undertaken only when chemical restraint is not available. Twitching should be regarded as a last resort of restraint, justified only as a means by which to inject a sedative or tranquillizer. Interestingly, the effects of a nose twitch can often be achieved by grasping and twisting a fold of skin on the side of the neck, presumably because this too causes pain and thus an **endorphin** response. Using this technique, handlers can often restrain fearful horses well enough to inject some form of chemical restraint. Hand twitches (taking the skin in the hand and twisting it) may be applied to the ear or skin at the side of the neck and, historically, tongue twitches were also used, but the consequence of **injury** in this case can be catastrophic (e.g. the tongue may be severed).

The **heart rate** of horses when twitched undergoes a transient increase (Morris, 1988) before returning to baseline values. This return to baseline is quicker in the crib-biters than in normal horses (Minero *et al.*, 1999). Although it is unclear why, **crib-biting** horses are said to be calmer during twitching and less reactive to the twitch in general than non-crib-biters (Minero *et al.*, 1999). These findings may reflect altered **dopamine** activity in the brains of these stereotypic animals.

U

UFAW (Universities Federation for Animal Welfare)

UFAW is an independent scientific and educational charity that promotes high standards of **welfare** for **companion, farmed, laboratory, zoo and wild animals**. It supports developments in the science and technology that underpin advances, holds workshops and symposia and advises regulatory authorities within and outside the UK. Its publications include the quarterly scientific journal *Animal Welfare* (see <http://www.ufaw.org.uk>).

(PH)

Ultimate factor

Ultimate factors refer to causes that favoured the **evolution** of a particular response in an animal, and are supposed to give **fitness**-related benefits to that animal. For example, an ultimate causal explanation of feeding would refer to it as a behaviour favoured by natural **selection** as a way to maintain an animal in good physical condition and thus to increase its potential reproductive success.

Ultradian rhythm

An ultradian rhythm is a biological rhythm that occurs with a frequency of less than one per day. Not surprisingly, the major biological rhythm in animals is the **sleep**/wake cycle, and many animals will have a single period of sleep/inactivity and a single period of wakefulness/activity each day. This cycle is endogenously generated, and many other biological processes are linked to this daily cycle but also have ultradian rhythmicity superimposed upon **circadian rhythmicity**.

Ultradian rhythms have been described in behaviour (activity), cardiovascular function, hormone release, body temperature, cerebral hemisphere dominance, nasal airflow and rapid-eye-movement (REM)/non-REM sleep. Activity-related ultradian rhythms are more common in neonatal and juvenile animals than in adult animals, and are characterized by bouts of vigorous activity interspersed with bouts of rest and/or sleep. In adult animals, ultradian rhythms of activity are closely related to feeding cycles and will be influenced by whether the animal is carnivorous, omnivorous or herbivorous. Environmental temperatures may also influence activity; for example, animals may show peaks in activity in the morning and evening, and avoid activity during the hottest part of the day.

Many hormones are secreted in a rhythmic, pulsatile fashion and, among those known to show ultradian rhythmicity, are **growth hormone, norepinephrine, dopamine, thyroid hormone** and cortisol. The rhythmicity is species dependent - for example, growth hormone peaks every 2-3 h in rats but every 5 h in calves. Similarly, cattle show cortisol peaks every 2 h, whereas rhesus monkeys have a rhythm of one every 90 min. Other physiological processes to show ultradian rhythmicity include **heart rate** and heart rate variability - indicating rhythmicity in autonomic function - and also rhythmicity in **electroencephalogram (EEG)** activity from the cerebral hemispheres. The cerebral hemispheres show alternating dominance, with activity switching from right to left and vice versa. This is accompanied by changes in the airflow through the nasal passages, known as the nasal cycle, which in humans has a periodicity of around 4 h. Throughout sleep, the body switches between REM sleep and non-REM sleep every 90-110 min.

Within the animal **welfare** field, ultradian rhythmicity has not received much attention, but some studies have looked for changes or disruption in biological rhythms in animals exposed to **stressors**. There remains scope for further research application.

Ultrasound

Ultrasound is sound pressure with a frequency above the threshold of human hearing - i.e. around 20 kHz and above. Within the animal sphere, ultrasound may either pertain to sounds emitted by some species for the purposes of **conspecific** communication or for **echolocation** of food, or to the medical sonography primarily used by animal caretakers to confirm pregnancy or examine specific tissues within the body. The terms 'ultrasound' and 'infrasound' are based purely on the human hearing range (20 Hz to 20 kHz), whereas many animals have normal hearing ranges that extend either below and/or above the human range. Higher-frequency sounds attenuate (lose intensity) more rapidly with distance and are susceptible to scattering and reflection by physical elements in the environment, but are more directional than lower-frequency sounds.

Ultrasound in communication

Ultrasonic **communication** has been documented throughout the animal kingdom, including insects, **amphibians**, mammals and birds. The properties of high-frequency sounds outlined above mean that, for communication purposes, ultrasonic calls may have limited value over longer distances. Among insects, many male moths are known to produce ultrasounds from special organs located in front of the tegulae, which produce a pulse of sound at up as high as 80 kHz on each wing beat. The sounds serve the dual purpose of helping to establish **territory** by keeping other males at a distance and also attracting female moths for mating. Some ants and some katydids have also been documented as being able to produce ultrasonic pulses, with potential **distress** signals, 'reassurance' **signals** and mating signals being emitted.

P.622

Within vertebrates, ultrasonic communication is well described in **rodents**. The ultrasonic calls of **rats** have attracted a great deal of research attention, and calls have been categorized into three distinct types. Rat pups will give characteristic 40 kHz **vocalizations** when they are separated from their mothers. Other rodent species such as **voles** and mice also emit these calls, ranging in frequency from 35 kHz to 55 kHz depending on the species, and invariably they result in the mother locating and returning the pup to the nest. Traditionally, these calls have been thought of as being emitted by the pup as a specific distress call meant to induce retrieval, but an alternative hypothesis is that they may be a by-product of an abdominal compression reaction in which abdominal muscles are contracted during expiration to help venous blood return to the heart, thereby maintaining cardiac output during **stress**. The larynx acts as a brake during exhalation and produces ultrasound. This hypothesis is still awaiting full testing.

Adult rats can also produce what are called 22 kHz vocalizations and 50 kHz vocalizations. The 50 kHz calls tend to be produced during **play**, non-aggressive social interactions and, by males, during copulation - i.e. during situations that may be emotionally positive. The 22 kHz calls are more associated with negative situations and have been recorded during aggressive interactions, in response to predators, when startled and in a model of chronic **pain**. They are also produced by the male during the post-copulatory phase. These calls have been widely used in psychological and pharmacological research as being an indicator of stress and, particularly, **anxiety**. As noted above, ultrasonic calls have properties that make them particularly useful as warning signals. Even though many predators such as canids and felids can hear up to 50 kHz, the fact that the calls rapidly attenuate means that rodents can signal to others in very close proximity to themselves without warning the predator that is further away. Producing lower-frequency calls as a predator approaches runs the risk of the predator being able to eavesdrop and obtain information about prey that may be nearby.

Other species known to produce ultrasonic calls with communicatory function are frogs, birds, toothed whales and bats. The latter two groups of animals use ultrasound primarily for echolocation, whereas the ultrasonic frog and bird species appear to have evolved their ultrasonic calls specifically for interspecific communication and under pressure from their habitat. Within any given environment, there are varying degrees of background noise. The noise may come from other animals or from abiotic sources, such as wind, rain or running water. The noise will have a certain frequency range, and the degree to which it interferes with the animal's call will depend on the overlap of this frequency range with the frequency range of the call. Much ambient noise, such as rushing water or traffic noise for example, may span the entire human audible frequency range and, thus, there may be selection pressure to shift the dominant frequency of calls above this range and into the ultrasonic range, even though the audible distance of the call may be lessened. Species of frogs and birds living by waterfalls, and even some birds in urban settings, are known to produce calls with ultrasonic components.

Toothed whales comprise the suborder Odontoceti of the order Cetacea, and include dolphins, porpoises, pilot whales, beaked whales, sperm whales and orcas. Many of the toothed whale species have a wide range of vocalizations used for

communicating with each other, including clicks, squeaks and whistles, and many of these contain elements in the ultrasonic band. All toothed whales so far investigated also produce purely ultrasonic clicks, which are used for both locating prey and navigation. It has recently been proposed that some elements of ultrasonic communication may have in fact derived from non-communicatory ultrasounds, i.e. the ultrasounds were evolved for one purpose but have been 'co-opted' for a role in communication. For example, bats are widely known as being highly ultrasonically vocal, as they use ultrasound for echolocation purposes in navigation and **hunting**. Consequently, bat hearing is acutely tuned to hearing ultrasonic sounds and is maximally sensitive over the frequency band of their echolocation pulses. It is therefore proposed that bats can use not only their own calls, but also that the calls of conspecifics can convey useful information. Bat ultrasonic calls have been implicated in synchronizing roosting behaviour, attracting each other to food sources and playing a role in mother-offspring communication. There is also evidence that echolocation calls can convey information about individual identity.

The ability of animals to hear ultrasound is also exploited by humans in both training (ultrasonic whistles for **dogs**) and in scaring unwanted animals away from human resources (ultrasonic deterrents for rodents, insects, **deer**, etc.).

Ultrasound in echolocation

Echolocation (or bio-sonar) refers to the ultrasonic sounds emitted by animals to ascertain the location, range and identity of objects in their environment. The principle is that the pulse of sound emitted echoes back from objects in the environment, being received by the animal's ears. The magnitude of the returning sound, the time taken to return and any differences in the timing of the return received by the ears provide information about relative size of the object, the distance from the animal and the direction of the object. The animal can then process the information and respond accordingly.

The best-known animal echolocators are the suborder of bats known as the Microchiroptera (microbats). These bats use echolocation both to navigate in the **nocturnal** environment and to locate and home in on prey. The sound itself is produced in the larynx and emitted through the open mouth or the nose. Microbat calls range from 14-100 kHz, and each species will vocalize using a narrow range within this general range that is suited to the environment and prey of that particular species. During the search phase of foraging, bats will call at 10-20 pulses/s. Once a target is located, call rate can increase and may reach levels of 200 pulses/s.

The other famous echolocators are the toothed whales. Toothed whales have a wide variety of vocalizations used mostly for social communication, but they also have a characteristic click that is used for echolocation. The source of these sounds is the nasal air sacs, which are located behind a specialized fatty tissue structure called the melon, which appears to focus the sound into a narrow beam. The clicks are emitted in a series, called a click train, and the pulse burst can contain more than 600 clicks/s, with individual clicks lasting between 50 and 130 μ s. The peak frequency of echolocation clicks is typically around 100 kHz, but varies depending on the specific echolocation task. The sound waves travel 4.5 times faster in water than in air, and the typical frequency clicks have

P.623

an effective range of between 5 and 200 m for targets of 5-15 cm in length. The echoes are received back through the lower jaw and transmitted up to the inner ear, with the animal responding based on the information received.

Other animals known to use echolocation primarily for navigational purposes are some species of shrew, the nocturnal oilbird and swiftlets. The birds, however, use clicks that are audible to humans, and are not thus classed as ultrasound. The shrews' echolocation is carried out using ultrasonic squeaks.

Ultrasound in veterinary medicine

Ultrasonography is widely used in both human and veterinary medicine. It can be used both as a diagnostic tool and a therapeutic tool. In diagnostics, it can be used as a non-invasive method of visualizing soft tissue structures. As with echolocation, the methodology is based on the transmission of ultrasound and interpretation of the reflected sound back from the tissue. The sound wave is typically produced by a piezoelectric transducer encased in a probe. Electrical pulses make the transducer ring at the desired frequency, which is usually between 1 and 18 MHz. Superficial structures are scanned using higher frequencies, while deeper structures are scanned using lower frequencies. The transducer also receives the echo, which in turn creates vibration that is turned into electrical impulses for processing and digital imaging. As a technique, diagnostic ultrasonic imaging has multiple applications but, within the veterinary field, it is most commonly

used to confirm pregnancy in domestic animals. It may also be used by veterinarians to diagnose disease, as in human medicine, and by animal scientists to determine production parameters such as back-fat depth and loin eye muscle area.

Pregnancy checking in domestic animals can help with the management of pregnancy - ensuring that care of the mother is tailored towards her gestational needs. The exact benefits will depend on whether the species is **companion animal** or **farmed animal**. With companion animals (such as pedigree dogs or competition horses), the mother and/or offspring may have high commercial value as well as emotional value. With farm animals, the commercial value of the individual animal is likely to be considerably less, but the collective financial well-being of the farm will be dependent on high proportions of successful conceptions. Many farms employ ultrasonic pregnancy checking as a management tool to ensure that 'open' females are not entered into the gestation herd or flock, but are either retained in the breeding system or culled due to reproductive difficulties.

Umwelt

Jakob von Uexküll (1936) termed an individual's entire subjectively perceived world its 'umwelt'. Umwelts differ between individuals, because sensory abilities differ and because stimuli have different relevance to each individual; Von Uexküll used the example of a flower stem being a path for ants, but a food morsel for cows.

Ungulates

Ungulates are the mammals that have replaced claws with hooves during their **evolution**. The surviving primitive ungulates are **elephants**, hyraxes and the armadillo. Fairly soon after they first arose, the ungulates diverged into even-toed (order Artiodactyla) and odd-toed (order Perissodactyla) ungulates. The asses, **horses** and zebras, the tapirs, and the **rhinoceroses** are perissodactyls and the **pigs**, peccaries, hippos, **camelids**, chevrotains and musk deer, **deer**, **giraffes** and bovines are

artiodactyls. Bovids comprise the pronghorn, wild **cattle** (bovines), duikers, gazelles and grazing antelopes, and goat antelopes.

All ungulates are terrestrial herbivores or omnivores. Specializations for a diet of plant material are evident in their teeth, jaws, digestive systems and behavioural ecology. A key feature is **rumination** (retention of food in a specialized stomach chamber system where it is fermented by symbiotic microorganisms), which most artiodactyls (but not the pigs, peccaries or hippos) employ to extract energy and nutrients from plant material. Perissodactyls have other adaptations - they house their symbionts in the hindgut, which is a less effective way of extracting energy and nutrients but is better able to cope with a coarser diet.

Many ungulates have social systems with strong social **bonding** and a clear **dominance hierarchy**. These, and other characteristics, suited them for **domestication** and they include the most important **farmed animals**.

(SJGH)

Urban wildlife

Urban wildlife is defined as animals that make use of resources (breeding habitat, roosting substrates, food, etc.) in urbanized areas. Urban wildlife includes a broad range of animals (e.g. house sparrows, Canada geese, pigeons, bats, **deer**, opossums, raccoons, etc.) that can have different degrees of association with humans.

Species highly dependent upon humans, particularly in terms of food (e.g. pigeons, **feral cats**, house **mouse**), are known as synanthropes. Synanthropes can be full synanthropes (also called exploiters or urbanophiles), which obtain most of their resources in urban areas, or casual synanthropes (also called adapters or moderately urbanophilic), which can adapt to exploit resources in urban habitats but also use other resources in more natural environments. Full synanthropes are generally found in areas with low vegetation within cities, but casual synanthropes do use urban vegetation for food or

P.624

nesting/**roosting**. Finally, species that are highly sensitive to urbanization (e.g. rare in cities) are called avoiders or urbanophobes.

Urban wildlife can be composed of native and non-native species. Native species are local species that use certain resources in urban areas, but they are also dependent on other habitats (e.g. casual synanthropes). Non-native species have been introduced locally from other ecosystems (or have colonized a local area after a regional introduction). Non-native species fare well in cities because of their high competitive ability and the high availability of foraging resources in cities. Two well-known examples are house sparrows (*Passer domesticus*) and European starlings (*Sturnus vulgaris*). The house sparrow, a native from Eurasia, was initially introduced to North America (in New York) in 1851. The species had expanded its geographic distribution to many states on the east and west coasts by the 1900s. Nowadays it is commonly seen **breeding** in cities, although it can also be present in farms and residential areas. Even more remarkable is the introduction of about 100 European starlings in New York in 1890, which expanded their distribution throughout North America with an estimated abundance of 200 million individuals. Part of the success of house sparrows and European starlings has been attributed to their ability to outcompete native species for nest cavities, which could result in the decline of native cavity-nesting species.

The role of urban wildlife is particularly important because of two worldwide trends in land use that are changing the representation of urban habitats. First, more than 50% of the human population is expected to be living in urban areas around the world by 2015. This increment in human density will be accompanied by even higher rates of urban sprawl, which will fragment and reduce the representation of natural habitats. Secondly, in some regions of the world there is an increase in the immigration rate to rural areas by people seeking lifestyles that provide closer access to natural areas (ex-urban development). Both trends are causing changes in land use that provide conditions conducive to the colonization of synanthropic species due to at least three factors. First, breeding and foraging resources increase around human settlements due to the presence of food leftovers, nesting substrates in buildings, etc. Secondly, natural predators are thought to be less abundant in cities, which would increase the survival of urban species, although further evidence is needed to support lower predation risk in cities. Thirdly, urbanized landscapes modify environmental conditions that minimize climatic fluctuations throughout the year, such as an increase in temperature (heat island effect) and water availability due to irrigation. These three conditions create similar urban environments in different regions of the world, which leads to homogenization of wildlife - an increase in the similarity of species composition across cities. Homogenization in turn can decrease species diversity at the regional level.

Variations in resource abundance, predation levels and environmental conditions along the rural-urban gradient modify species richness and abundance. Generally, the number of native species decreases, and the number of non-native species increases, with increasing levels of urbanization. Because of these opposing patterns, the overall number of species tends to peak at intermediate degrees of urbanization. This inverted U-shape pattern has been found in birds, small mammals, lizards and butterflies. In birds, a few synanthropic species tend to dominate urban communities due to their extremely high densities relative to other habitat types. These birds are usually ground-foraging seed eaters or omnivores that have adapted to nesting in human substrates. In mammals, synanthropic species that reach the highest densities are often found inside buildings.

Urban sprawl can modify ecological relationships, such as predator-prey interactions. Fragmentation of natural habitats reduces the size of the remnant patches, which can decrease the densities of top-predators, or drive them to local extinction. For instance, in coastal southern California, coyote populations have dwindled due to the high degrees of urbanization around native sage-scrub habitat. The lack of this top-predator increases the abundance of native (raccoon, grey fox) and non-native (domestic cat, opossum), low-level predators, a process known as **mesopredator** release. This intensifies the negative effects of habitat fragmentation on native scrub-breeding birds because low-level predators, especially the domestic cat, have high abundances in small-sized remnant patches, thereby increasing local bird mortality due to **predation**.

The overlap in spatial use by humans and wildlife in urbanized areas generates different types of conflicts. The overabundance of some species can damage private and public property, increase road danger and spread diseases. For instance, the accumulation of pigeon faeces can block rainwater drainage systems, decrease the aesthetic value of buildings - particularly those of cultural relevance - and increase slippery footing on walkways. Deer collision with vehicles is probably enhanced by increasing deer abundance, expanded road networks, greater traffic load and high average vehicle speeds. This results in around 1.5 million deer-vehicle collisions yearly in the USA. Finally, urban wildlife species that are hosts of infectious **diseases** (e.g. West Nile virus, avian influenza, Lyme disease, etc.) can increase the chances of transmission to humans in the presence of vectors. Wildlife managers and public health officials have developed various strategies to minimize the risks of transmission by **culling** different species or reducing the availability of resources (e.g. water for mosquito breeding).

In conclusion, urban wildlife encompasses a diverse set of species that require to be managed in different ways according to their degree of association with humans. Despite conflicts, the presence of wildlife in cities not only brings ecological but also psychological benefits by providing humans with the opportunity to experience the natural environment. To maintain these benefits, it is important that the diversity of native vegetation is enhanced in urban areas.

Urine

Urine is an aqueous solution of waste materials from metabolic processes in the body. Blood passes through the kidneys, where it undergoes filtration. Metabolites are secreted along with water into the ureter. The urine then travels down the ureter into the bladder, where it is stored until the animal urinates - expelling the urine out of the bladder through the urethra. From a physiological aspect, the production of urine is important in **homeostasis**, to maintain the water balance within the body. With dehydration, water is conserved as blood passes through the kidneys and urine volume decreases and becomes more concentrated. With subsequent rehydration, water will be removed in larger quantities and urine volume and dilution will both increase.

From welfare and behaviour aspects, urine can have an important role in intra- and interspecific **communication**; it can contain **stress** markers that can be collected non-invasively; and it can impact **welfare** in relation to hygiene and air quality. Mares' urine is also used in the manufacture of the drug used in **oestrogen** replacement therapy, and there have been concerns about the welfare of the horses involved.

Urine and communication

Chemicals contained within urine, and sensed by the olfactory system and the **vomeronasal organ** (VMO), can convey a variety of information that can have an effect both within and between species. Urine can convey information about individual identity, social **dominance**, territorial limits, reproductive status, predator/prey proximity and even emotional states, such as **fear**. One source of information about individual identity is most probably conveyed by soluble antigens of the major histocompatibility complex (MHC) reacting with bacterial flora to produce volatile compounds that give the urine a characteristic odour. Another mechanism involves major urinary proteins (MUP), which bind and release volatile compounds, and have been well described in rodents.

Experimental studies have shown individual **recognition** using urine in many species - for example mice, rats, bank voles, hamsters, lynx and pigs. For social dominance, **androgen** hormones and metabolites appear to be an important element in conveying information; and in rodents, relative dominance may be conveyed by the quantity of urine scent marks left within a **territory**. More dominant mice make more urine marks, whereas subordinate mice make fewer marks. Territorial marking by many species often includes urination around territorial boundaries, in combination with visual markers such as scratching. Within domestic species, territorial urine spraying in cats can become a problem behaviour that necessitates intervention to remedy.

Urine has long been known as a conveyor of information about reproductive status. Male urine, as noted above, can convey information about territory and dominance, and can act as an advertisement or attractant to females seeking a mate. Female urine can contain information about stage of **oestrus**, and thus a female's receptivity for mating. A number of urinary volatiles have been shown to peak during oestrus in a variety of species. A characteristic male response to female urine, particularly obvious in ungulates, is that of **flehmen**, a certain type of lip curling thought to facilitate use of the vomeronasal organ.

There are a great many studies that have shown that urine from a predator species can be detected and discriminated by prey species, which subsequently alter aspects of their behaviour, presumably to decrease risk of predation. The most common predator species used have been felids, canids and also humans. The most common prey animals tested have included rodents and lagomorphs, but also marsupials and ungulates. Behavioural strategies that may occur in response to predator odour include decreases in activity and behaviours such as **grooming** and **reproductive behaviour**, shifts to a more strategic location and increases in vigilance. Temporal patterns of behaviour may also change with alteration of feeding times.

Urine and stress markers

One of the major problems with gathering physiological data relating to responses to stress is that the collection of such data may itself be a **stressor**. For example, collection of blood for stress hormone analysis will either involve the implantation of an indwelling venous catheter under anaesthetic or **restraint** of the conscious animal and insertion of a needle to draw the blood sample. Both of these methods can be considered invasive and, thus, there has recently been an

upsurge in experimental work looking at alternative body fluids, such as saliva and urine, which can be collected in a much less invasive way.

Among the compounds analysed in urine and used as stress markers are cortisol, cortisone, **epinephrine**, **norepinephrine** and immunoglobulin A (IgA). The use of urine collection has been especially popular in studies involving **companion animals**, such as cats and dogs undergoing boarding at catteries and kennels, and in **laboratory animals** undergoing experimental procedures. It has also been used in a number of studies on welfare in pigs. Ideally, samples are collected as the animal urinates freely (voluntary voiding).

Urine and welfare in animal housing

Animals other than those that are free-ranging are, to a greater or lesser extent, constrained in terms of elimination behaviour. The degree of constraint will largely depend on the degree of spatial restriction - pigs in a small pen will be more constrained than pigs in an enclosed paddock. Ordinarily, most animals will choose to separate themselves from their faeces and urine and may allocate specific areas of their habitat for elimination. For domestic species, **housing** invariably disrupts normal eliminative habits and, thus, animals may be unable to separate themselves from their own waste. This can impact the animals' welfare, either by forcing them to be exposed to substances that may be ordinarily avoided, by exposure to situations that challenge comfort and **thermoregulation** or

P.626

by exposure to potential **health** hazards, either by direct contact with pathogens or through indirect effects of poor air quality, in particular ammonia.

Farmed animals and laboratory animals are perhaps the most impacted by the housing systems in which they are kept. For farm animals, the housing system will either attempt to delineate areas within the pen into **lying** areas and dunging areas by use of relatively small amounts of bedding applied to one area, or it may aim to remove the animals from their waste by utilizing slatted floors so that urine and faeces fall through into a slurry pit. Alternatively, the pen may be deep bedded, with fresh bedding added on top of existing bedding until the animals are moved out after a period of weeks or months. In all these situations, the animals will be unavoidably exposed to their own urine and faeces, and to that of their pen-mates. Once in the environment, urine will react with bedding and faeces to produce ammonia, and this can be present in harmful concentrations in farm animal housing with insufficient ventilation. Wet bedding can also have a negative impact on pen hygiene and pathogen load, affecting illness incidence such as increased respiratory disease in calves or behaviour - for example, reducing lying time in dairy cows. For laboratory rodents, there have been some concerns raised that frequent cage cleaning to remove urine may have a negative impact by disrupting the rodents' olfactory environment. However, recent studies suggest that frequent cleaning has little impact on rodents' welfare.

Urine and pregnant mares

A drug containing conjugated **oestrogens** is manufactured from the urine of pregnant mares. It is used as a form of hormone replacement therapy during menopause and by women who have undergone hysterectomy. Welfare concerns over the housing of the horses used to produce this hormone, i.e. the use of tie stalls, and the fact that many of the foals born to the mares were sent for **slaughter**, have been raised as objections to the process. In the last couple of decades, the industry has downsized as synthetic oestrogens have become more widespread, and also has adopted a welfare code of practice that must be followed for the ranch to maintain its contract, with non-pregnant mares having access to pasture for many months of the year. A few studies carried out on mares in these systems have not found any major welfare problems.

Urine drinking

Urine drinking, urophagia, is usually a form of **pica**, a depraved or **abnormal** appetite, and can be considered an abnormal behaviour. It is believed to usually derive from nutrient deficiencies or other **stresses** in animals, but also occurs in males testing for **oestrus pheromones** in females, e.g. in dogs and cattle. The behaviour may involve direct drinking from the anovaginal area of females or from the penis of males, or from pools on the ground. It has been most commonly observed in overwintering cattle indoors. The effects on production levels and herd health are small, but infectious agents, such as *Leptospira* and *Mycobacterium tuberculosis*, can be passed from animal to animal in this way. However, urine directly expelled contains urea, which has antibacterial and antifungal properties.

Urine-drinking behaviour has been observed in group-housed calves as an extension of cross-sucking behaviour (Lidfors, 1993) (**see: Cross-suckling**), and in piglets that have been experimentally challenged with regard to their salt balance (Benda *et al.*, 1998). **Wild animals** also show this behaviour, and it has been reported in colobus monkeys (Rode *et al.*, 2003) and African tree monkeys (Lambert, 2000). The fructivorous diet is low in minerals and it is postulated that, in this case, urine drinking is a strategy to minimize mineral losses, of sodium in particular - an idea that would appear to be further evidenced by the aforementioned work on salt-challenged piglets (Benda *et al.*, 1998). There may also be a role for urine drinking in nitrogen balance.

Urine marking

Urine marking involves the use of urine as a scent mark to denote the individual's identity, presence or status or to mask the presence of others (for example in the marking of **territory** or **home range**). Urine marking can sometimes be discriminated from eliminative urination by the volume of the urine expelled and possibly the **posture** of the animal. In many species it can occur in either sex (and in neutered animals) but tends to occur more often in entire males. **Dogs** may mark by raising one hind leg against a vertical object ('raised leg urination', RLU), **cats** may back up against a vertical surface with an erect, quivering tail. This may not only serve as a visual display but also help to make the smell more noticeable to other individuals by placing it nearer to head height.

Urine washing

Urine washing, where an animal urinates on the palm of the hand, and then wipes their hand on the soles of their feet, is a

P.627

behaviour that has been observed mainly in primates. It may have thermoregulatory benefits as well as disinfecting properties for the skin and coat, especially aiding wound healing.

(DA)

Utilitarianism

Utilitarianism is a consequentialist ethical theory that specifies that the rightness or wrongness of an action depends entirely on the outcome that it produces. Utilitarianism directs us to promote the greatest total amount of good or best possible balance of benefits over harms for all those affected by the action. In the case of animal welfare and ethics, this approach contends that we are justified in using animals if - and only if - the overall benefit to humans and animals is not outweighed by the harm done to animals, and there is no other more efficient 'optimific' way of achieving the same result.

(RA)

Utilization distribution

The utilization distribution of an area is the probability distribution that refers to the likelihood of the location of an individual within a given area at any time. Areas of highest probability within a territory often make up the **core area**, with the **home range** being a more extensive area that is also used routinely (i.e. has a relatively high level of probability with the utilization distribution). Certain areas may vary in their probability of use depending on time-bound or physical factors, such as season and availability of relevant resources.

V

Vacuum behaviour

An action that occurs in the absence of the external stimulus that usually initiates it. Such behaviours are usually **instinctive behaviour** patterns that the individual is highly motivated to perform, but where the appropriate outlet is absent. As such, the behaviour appears to serve no obvious purpose in its current context. For example, **dust-bathing** behaviour observed in hens when no substrate is available (Vestergaard, 1980), or in circling before **lying** down in the house by dogs. The **welfare** implications of vacuum behaviours are variable and need to be assessed on a case by case basis.

Validity

In science 'validity' is used mostly as a term to describe the quality of a test or measuring procedure. A test or a procedure is considered valid if it succeeds in *measuring what the researchers set out to measure*. Often the validity of a specific test or procedure is assessed by comparing how well its results match the results of other tests or procedures designed to measure the same thing. In **logic** and philosophy, validity attaches strictly to *arguments*. In a valid argument the conclusion is logically *entailed* by the premises. It is important to appreciate that such entailment is no guarantee that one has made a good argument: it can easily generate a false conclusion if the relevant premises are false. Only if true premises are used will validity secure a true conclusion. A valid argument with true premises is best described as cogent, or sound.

Variation

Variation refers to the instance or magnitude of change within any biological level. Species inhabiting different or variable habitats usually have a higher degree of inter-individual or inter-population variation than species localized in a single, stable habitat. Examples of variation may be the variable degree of difference in body size between males and females of a given species or the number of alleles for a single locus.

Vasopressin (antidiuretic hormone (ADH))

Vasopressin is a peptide neurohormone that is produced by the **hypothalamus** and released into the circulation from the posterior **pituitary gland**, which regulates circulatory pressure by constricting blood vessels and increasing water resorption in the kidneys. Two related forms are commonly recognized in mammals: arginine vasopressin and lysine vasopressin, the latter being the normal form found in pigs and marsupials, the former the more typical form in other mammals. The equivalent compound in birds is called vasotocin. Interest has grown in vasopressin recently as a potential mediator of certain forms of emotional **stress**.

(DSM)

Veganism

Some adherents of moral veganism oppose the consumption of all animal products because they believe that, because animals experience many of the same physiological and emotional states as humans and can suffer the harm of **death**, commitment to true humanity involves extending the circle of compassion to include all living things and ending institutionalized cruelty of animals. Others may be vegans out of concern for the environment and for unjust social practices associated with animal agriculture.

(RA)

Vegetarianism

The philosophical underpinnings of those committed to ethical vegetarianism are diverse. Some adherents protest against the use of animals as mere things to be exploited for human benefit in ways that make animals and their products cheaply and abundantly available. They disagree with the justification behind the infliction of **suffering** and **death** on animals for meat, eggs, milk and other by-products.

One variety of ethical vegetarianism contends that our obligation be based on respecting the moral status of animals. This variety can be divided into two overlapping but distinct sub-strands:

- Animal **welfare** utilitarians stress that we have a duty to boycott animal products as long as the way animals are

P.630

raised promotes excessive suffering. Their boycott is due to the confined conditions of poultry and swine, for example, which suffer from severe restriction of movement and inhumane **slaughter**.

- **Animal rights** vegetarians contend that vegetarianism is morally required because a meat-based diet violates respectful treatment of animals, especially adult non-human mammals. These animals are rights-holders and have inherent value. Killing them is wrong because it deprives them of a future life they would have enjoyed. Giving animals pleasant lives or painless deaths does not truly amount to respect.

Other varieties have emerged, which can be linked to environmentalist or social justice movements. Under the former view we should adopt vegetarianism, or at least reduce our meat consumption of animal products, because of the catastrophic environmental impacts of large-scale animal agriculture, including the pollution by toxic animal wastes of air, streams and groundwater, and deforestation. Under the latter view a Kantian vegetarian, while discounting the independent moral worth of animals, would contend that subscribing to a meat-based diet effectively treats humanity simply as a means and not as an end in itself. They contend that there is enough scientific evidence to show that a meat-based diet high in animal fat is not healthy, and that a vegetarian diet prevents diseases. Hence, continuing such a meat-based diet conflicts with the duty to promote one's **well-being**. Others, like Kathryn Paxton George, argue to the contrary that meat consumption is one

of the most efficient ways for women to prevent iron deficiency. Moderate vegetarians, namely lacto-ovo and demi-vegetarians, approve of some animal use as long as good animal welfare/care practices are fastidiously observed.

Vices

The term vice is used in two distinct ways in relation to applied animal behaviour and animal **welfare**. In Aristotelian **virtue ethics**, vices result from choosing excesses with respect to emotional states and desires. Vices are distinguished from involuntary actions - actions performed under compulsion or in ignorance, for which the agent did not deliberately contribute to that act. From the perspective of virtue ethics, intentionally causing harm to animals is seen not so much as a violation of the animals' rights per se but as a character flaw of the perpetrator.

The term 'vice' is also commonly used to describe the repetitive behaviour of animals in **confinement**, most notably behaviours such as **weaving** and **crib-biting** in the **horse**. This use of the term is discouraged in the literature because of confusion with its use in virtue ethics, which may bias thinking about these behaviours as a defect primarily in the animal, rather than arising as a consequence of its husbandry (**see: Stereotypes**).

(RA)

Video image recording and analysis

The use of video recording equipment has greatly increased the ability to observe, capture and analyse many aspects of animal behaviour. The ability to place a camera out of sight has enabled researchers and wildlife filmmakers to record elusive species and behavioural sequences and to minimize the impact of the observer on these. The use of time lapse and long-play videotapes has allowed researchers to record behaviours over relatively long periods without having to be physically there, saving them time and money. The video camera has also increased the detail with which behaviour can be recorded and analysed by enabling the researcher to make more careful observations of the behaviour in the laboratory, with the videotape slowed or paused to catch fast or complex behaviours. Special high speed video recording is necessary for capture of particularly rapid behaviour. Video recording has also facilitated the ability to test **inter-observer reliability** and **intra-observer reliability**. Over-reliance on the use of video cameras, however, can adversely affect a piece of research when, for example, equipment fails or behaviours are out of view or not in focus and cannot be recorded properly.

The use of computerized event recorders in conjunction with the playback of a videotape can speed up and increase the detail and reliability with which data can be recorded during an observation. Preliminary observations are required to identify the behavioural events or states of interest and to give these, and the individuals performing them, a code such as a key on the computer keyboard. The observer then watches the video and presses keys to identify an individual or the start of a behaviour. This may be done continuously as in a live observation or by using predefined intermittent time points. The use of event recorders allows the user to pause during an observation or to repeat observations if they feel they have made a mistake. The raw data can then be moved directly into a data analysis package, minimizing the risk of error at this stage. However, the more sophisticated event recorders now available can also perform preliminary analysis of the data, including giving the percentage of time spent in each behaviour and the reliability between observers.

Vigilance

In general terms, vigilance is alert observation to detect objects or events in the surrounding environment (**see also: Arousal**). When in a highly vigilant state, animals actively scan their environment with heightened sensory perception to increase their chance of detecting a subject of interest. Once detected, this **stimulus** elicits a corresponding response by the animal.

P.631

However, the level of vigilance and reaction can vary. For example, antelope as well as other ungulates will occasionally lift their heads from the ground to look around, visually surveying the surroundings while foraging. If disturbed or danger is sensed, an extreme alert posture may be formed, with the head up, nose lifted, ears erect and oriented towards the disturbance. In both situations, vigilance is occurring but at different levels.

Animals are able to enhance their vigilance by increasing the rate and length of scans, engaging in vigilant behaviour more frequently and for longer periods. While having increased vigilance confers advantages by providing critical information useful for an individual's response to its environment, animals cannot remain at a constantly high vigilant state. There are two main reasons for this: (i) detection efficiency tends to decrease over time; and (ii) physiological constraints. Human subjects have been shown to tire under sustained vigilance, making more false alarms or fewer correct detections as time increases. Increased vigilance also can be energetically costly to an individual by reducing their food intake rate. Trade-offs between time spent being vigilant and time spent performing other necessary activities, such as feeding, must be made in order to maximize **fitness**.

Vigilant behaviour can serve several purposes for an organism: predator detection and **predator avoidance**, social interactions, mating and location of food or other resources. The role of vigilance in predator detection has received considerable attention. Animals are known to alter their behaviour in the presence of predators, including increasing vigilance. Early detection of predators is obviously advantageous to allow a quick response and avoid being eaten. Multiple factors can influence anti-predator vigilance such as predation risk, habitat, refugia, presence of young, group size, location and distance to **conspecifics**, and body size.

In areas where there are many predators and the risk of predation is high, vigilance is increased in order to lower that risk. Certain habitat types can pose greater risk to some species. While dense cover can provide refugia for some, it can also obstruct visibility, reduce mobility and provide hiding cover to predators. Large ungulates have been found to be more vigilant in dense cover than in open grassland habitat, whereas the opposite may be found for other species, depending on the proximity to refugia for escape and the particular behaviour of the predator (e.g. stalking or ambush behaviour of mountain lions, aerial dives of hawks). **Parental behaviour** also has a tremendous effect on vigilance. Adults caring for offspring typically increase vigilance to protect their investment and decrease the risk of mortality for their defenceless young. However, the time required for anti-predator vigilance can place a huge demand on a single individual's activity budget (**see: Time budget**).

One strategy to reduce the cost of vigilance is to forage in **groups**. Among social vertebrates, collective vigilance tends to be positively related to group size, while individual vigilance decreases with increasing group size. Each individual forager can devote more time to feeding and less time to vigilance when in a group because there is a greater chance that at least one individual in the group will detect the predator. This has been called the 'many-eyes' hypothesis, based on the greater number of eyes available to scan the environment as group size increases. The effectiveness of this strategy, however,

depends on the maintenance of collective vigilance, despite lowered individual vigilance, and the ability of the whole group to be alerted once a predator has been detected. Alarm calls are often used to communicate a detected risk among group members, conferring the benefits of vigilance to the entire group. Similarly, herding behaviour may decrease the risk of predation due to a dilution effect. An individual's probability of being attacked is reduced in a group, since the predator can only target one prey per attack.

As distance to **conspecifics** increases and individuals become more isolated, vigilance tends to increase. Based on the selfish herd theory, the centre of the herd may have the lowest risk of predation. Correspondingly, individuals near the centre tend to be less vigilant compared with individuals located on the periphery of the group. Body size also appears to be a factor in the level of vigilance observed. A negative allometric scaling relationship between body size and vigilance was found for African antelope. This could be due to lower predation risk to larger-sized animals, greater efficiency of vigilant behaviour or the higher cost of vigilance due to time constraints on foraging needed to meet their energetic requirements.

Besides functioning as an anti-predator behaviour, vigilance also plays a role in social interactions and **communication**. For example, dominant males survey their territories to prevent intrusion from other males. In harem-based mating systems, a male may watch over a group of females to maintain and protect the harem from outside copulations. Vigilance can also help to detect and locate potential mates. In addition, vigilance may be directed at other conspecifics to help determine spacing and minimize intraspecific competition within a foraging group.

Finally, vigilance can assist with foraging by scanning the environment for suitable or preferred food items. As with anti-predator vigilance, the time spent being vigilant can incur a cost and reduce food intake rate, unless an animal can combine searching with handling food. By processing food while searching for the next bite, vigilance costs can be reduced, particularly in areas of high food biomass. Animals may also decrease search time by forming a search image or **gestalt** of their preferred items to facilitate a selective search for those items distributed across the environment.

Of course, these different functions of vigilance are not mutually exclusive. Animals can detect multiple stimuli and direct their behaviour accordingly. The primary goal of vigilant behaviour, however, remains the same - effective detection within one's environment.

Virtue ethics

Virtue ethics holds that morality consists of the exercise of virtues - settled dispositions of character founded on reasoning well about emotional impingements and desires.

P.632

Aristotle (384-322 BC) serves as a main source of inspiration for this agent-centred view of ethics, which highlights moral agents and their lives instead of actions or obligations per se. Virtue ethics approaches encourage those who interact with animals to cultivate the virtues of compassion, generosity, care and empathy.

Visual perception

Visual perception constitutes the ability to detect light as it reaches the eye and interpret the information contained within it, the resulting perceptual construct being known as sight or vision. Visual perception relies upon light reflected from

surfaces in the environment; different colours and textures absorb and reflect different wavelengths of light, these then entering the eye, often passing through a lens which focuses them upon a photosensitive area, e.g. the retina of vertebrates and the eye of the octopus being an example of convergent evolution. The retina acts as a transducer, converting light into neural impulses, which are sent via the optic nerve to the lateral geniculate nucleus and visual cortex for processing. Sampling of the optic array is achieved through rapid movements of the eye, saccades, followed by fixations upon a specific object and smooth pursuit movements that facilitate tracking.

The retinae of most diurnal species contain two types of photoreceptors: (i) rods, which respond to low levels of illumination, allowing the perception of achromatic colour (scotopic vision); and (ii) cones, which respond to levels of brighter light and enable the perception of chromatic colour (photopic vision or colour vision). The number and type of cones in the retinae vary across species, determining the visible colour spectrum. Most mammals have two types of cone, some primates and marsupials have three while birds can have as many as six. The distribution of photoreceptors across the retina also varies across species, affecting visual acuity. In primates the highest density of cones is found near the centre of the retina in the fovea, allowing objects in frontal vision to be viewed with maximum clarity; however, in many other species including many domestic mammals, photoreceptors are most densely distributed in a horizontal band across the retina, the visual streak, this providing enhanced detection of movement across the visual field. However, in some species there is variation in the distribution, which appears to correlate with muzzle length, and thus short-nosed breeds of dog (brachycephalics) may have more of a fovea, while longer-nosed breeds (dolichocephalics) may have more of a visual streak.

The positioning of the eyes in the head influences visual perception, with frontally located eyes - typically found in predators - providing a narrower field of view than that afforded to species with more laterally positioned eyes, usually in prey species, that allow greater peripheral vision. The overlap, however, between the fields of vision of frontally positioned eyes allows a larger proportion of the visual field to experience depth perception through stereopsis, based upon the correspondence between the slightly different images delivered to the **brain** from the two eyes.

As the perception of the environment is influenced by the components of the visual system and the processing performed by the brain, it is useful to distinguish between the environment surrounding the individual and its **umwelt**, the environment as it is perceived by a given individual, which is what determines responses to visual stimuli.

Vivisection

Literally meaning ‘cutting up alive’, the term was applied to the very invasive research carried out before **anaesthesia** was first discovered in 1845. Before then, animals were literally tied down or nailed to a table or floor so they could not move during the experimental surgery. Animals were used to further knowledge of anatomy and function, to demonstrate known facts before the public or as a part of an educational process, e.g. the training of veterinarians in anatomy. Groups who describe themselves as antivivisectionists are generally opposed to the use of animals in all experiments, whether or not the work is invasive or causes **suffering**.

(DBM)

Vocalization

Vocalizations are sounds produced by animals via their vocal tract. Thus, vocalizations can be considered a subset of acoustic **signals**, different from other animal sound such as those produced by crickets when rubbing together the striated surfaces of their wings. All sound is produced as a result of vibrations. The animal may modulate these sounds - for example, filtering and resonating different frequencies as the sounds pass through the vocal tract.

Vertebrates produce vocalizations by forcing air through a tube. The tube is constrained by membranes, constricting airflow and causing the membranes to vibrate. In mammals the vocal apparatus is called the larynx, and the vocal cords (glottis) block respiratory airflow to create vibrations. In birds, the analogous structure is called the syrinx; this structure consists of two sides that can independently produce sounds.

In birds, authors typically distinguish 'songs' from 'calls', with songs typically being longer and more complex than calls. Songs are also learned, while many calls can be produced with little or no learning. Calls are typically associated with a wide range of functions, such as the 'begging' calls that nestlings use to solicit parental care, or the 'alarm' calls used to alert others to the presence of a potential predator. In contrast, songs are used for intra- and intersexual **communication**; for example, male birds sing to advertise territorial boundaries to male rivals, or their quality as a potential mate to female listeners.

Vocalizations and other acoustic signals can be described in terms of the wave properties, including amplitude (typically measured in dB) and frequency (typically measured in Hz). More complex vocalizations can be broken down into component 'notes' or 'syllables', and each of these may vary in

P.633

frequency or amplitude over time. Changes in frequency in time can be visualized using a spectrogram. Although historically many vocalizations have been classified according to gross spectrographic features, e.g. distinguishing a bark from a growl, from a whine, etc. in the dog, vocalizations within a given type may vary content with meaning; for example, different types of bark in the dog, are reliably associated with different contexts when they would be expected to convey different meanings. The use of computer algorithms offers a reliable way of characterizing the consistent features of different types of vocalization, opening up the way to a deeper appreciation of the range of auditory signals used in vocalization and other means of acoustic communication.

Vomerolateral organ

The vomeronasal organ is also known as Jacobson's organ. It consists of a small, paired, tubular structure in the nasal cavity, lined with ciliated epithelium and including chemoreceptors and a collection of **neuron(s)**. In mammals it is located in the septum and in **reptiles** in the roof of the mouth. It is present in most vertebrate animals. It develops in the **fetus** in man and higher primates, but is thought to subsequently regress, though opinions vary. It is present in most **amphibians** and reptiles, though not in the crocodile nor chameleon, and it is also absent in birds and fish, where the vomeronasal receptors are located in the olfactory epithelium.

It usually has a narrow range of receptors that respond to a small range of compounds (**pheromones** and possibly some other large molecules), far fewer than the more general olfactory receptors. The vomeronasal organ is not only anatomically distinct from the olfactory receptors, at least in tetrapod vertebrates, but is also linked to a different part of the **central nervous system** (accessory olfactory bulb). This suggests not only a difference in function but also a difference in evolutionary origin - probably evolving first in the **amphibians**.

The vomeronasal organ stimulates behavioural responses to pheromones, especially related to **sexual behaviour** and the mediation of reproductive status, but its role in other behaviour systems is increasingly being recognized. Male and female **rats**, **guinea pigs** and **hamsters** whose vomeronasal organs have been surgically isolated no longer exhibit sexual behaviour (including the defence of territories). The mechanism for this is probably through the mediation of the release of **gonadotropin-releasing hormone (GnRH)** - and therefore the release of **luteinizing hormone (LH)**.

In amphibians and some reptiles it is also related to predator and prey recognition. The amphibian vomeronasal system has further been shown to respond to chemical cues released by injured or alarmed **conspecifics**. Pheromones are detected by passing inspired air over the vomeronasal organ, exemplified by the **flehmen** response (demonstrated by the equine, bovine, ovine and feline species), licking and teeth chattering (canids), touching the organ with the tongue (snake species and the komodo dragon), nose-bobbing (salamander) or, in the frog, showing no behavioural act, the cilia simply wafting introduced water across the vomeronasal organ.

Von Frisch, Karl Ritter

Karl von Frisch (1886-1982) was born on 20 November 1886 in Vienna, the city where he also began his university studies initially in medicine, although he later switched to zoology (studying in both Munich and Vienna) and was awarded his PhD from Vienna in 1910. Much of his academic life was spent associated with Munich. He was jointly awarded the Nobel prize for Medicine or Physiology in 1973 with **Konrad Lorenz** and **Niko Tinbergen**, in recognition of his work on honeybees. He is largely recognized for having elucidated the honeybee dance as a means of navigational **communication**, but he studied the sensory system of bees more widely. This included demonstration of their colour vision and the role of the **pheromones** produced by the queen in the regulation of the hive. In addition to his reputation relating to bees, he also published on various aspects of marine biology.

W

Weaned pig (weaner)

A weaned pig is a pig that is permanently deprived of suckling from the sow's udder. Before weaning, pigs rely on maternal milk for nourishment, though solid food may be gradually introduced. Naturally, **weaning** is gradual as milk consumption decreases and solid food consumption increases over time until pigs are fully weaned, at between 8 and 17 weeks of age; in swine production systems pigs are weaned abruptly, usually between 2 and 5 weeks of age.

(RP)

Weaner

A weaner is a young animal that has been recently weaned from its mother - i.e. it is no longer nutritionally reliant on maternal milk or, in a husbandry setting, has been artificially deprived of maternal milk by maternal separation. The term is most often used for piglets (**see: Weaned pig**), but is also used for calves and lambs. For piglets, a weaner is a pig usually between the ages of 3 and 8 weeks of age. The bottom end of the scale will vary depending on the exact age of **weaning** - it may be as early as 2 weeks of age or as late as 5-6 weeks of age, depending on the system. The top end of the scale is fairly static, however, and after this age the piglet becomes a grower and then a finisher. For calves, weaning age will differ depending on whether the calf is a dairy calf or a beef calf. For dairy calves, weaning is usually around 6-8 weeks of age, although they are separated from the cow at between 1-4 days of age. Beef calves are usually reared on the cow up to the age of 6-8 months. For lambs, the usual weaning age is around 2-3 months, but may be much earlier in dairy **sheep**. In all cases, weaning under commercial conditions occurs quite differently to natural weaning. It occurs early and it is abrupt, with a sudden change from milk to solid feed, separation from the mother and often mixing with unfamiliar animals. The process is therefore considered to be particularly stressful for the weaner, and there are a number of welfare issues that have been subject to research.

Weaner pigs

The normal weaning age for piglets is anywhere between 8 and 19 weeks old. Under natural or semi-natural conditions, weaning is a gradual event. In effect, natural weaning starts early on in **lactation**. The frequency of suckling declines gradually from the first week, and the number of suckling events terminated by the sow increases, perhaps indicating that the sows become less inclined to nurse. Piglets begin to consume solid food from around 4 weeks postpartum and, by 8 weeks, solid food constitutes a large part of the piglets' diet. The number of piglets missing from suckling also gradually increases and weaning is completed anywhere between 8 weeks and 19 weeks postpartum, and there can be quite large variation in weaning age occurring within a given litter. Piglets also mix with piglets from other litters from around 2 weeks of age. Under commercial conditions, weaning occurs anywhere from 2 to 6 weeks of age and most typically at 3-4 weeks. At this point, piglets are most likely removed from the sow and placed into a new environment - the nursery accommodation. They may be kept as a litter or mixed with other litters weaned at the same time. In North American systems in particular, weaner pigs may also be subjected to long-distance transportation at weaning, with truck trips of hundreds of miles from the breeding farm to the rearing farm.

Major factors that affect the **welfare** and behaviour of weaner pigs include: weaning age, group size, group composition, space allowance, floor type, feeding system and thermal environment. A variety of **housing** systems are used for weaned piglets. Piglets are typically housed in highly controlled environments with supplementary heating in partly or fully-slatted pens or raised in flat decks in groups of varying sizes (10-40). They may be moved from the first-stage weaner accommodation to larger, second-stage accommodation after 2-4 weeks or remain in the same pen until the age of 8-10 weeks (30-40 kg) or, in a few instances, until **slaughter**. The pen area per pig varies from 0.2 (<20 kg) to 0.3 m² per pig (<30 kg). Weaner pigs are typically fed *ad libitum* (dry) or restricted (liquid) with an animal: feeder space ratio of 1:1-12:1,

depending on the feeding system. Within nursery accommodation, the ambient temperature recommended and generally used (non-bedded, perforated floors) is in the range of 26-30°C, e.g. a temperature of 28°C for piglets weaned at 26-28 days of age.

The age at which piglets are weaned makes them particularly susceptible to disease. At around 3 weeks of age, a piglet's immune function is at its lowest. The protection afforded by maternal antibodies is by now very low, and its own immune system is just beginning to become functional. The challenges of a new environment, new pathogens, **social stress** and poor nutrition can have a large impact on piglet health around this time, and they become particularly prone to enteric disorders. Most of the bacterial pathogens associated with post-weaning enteric disorders are strains of enterotoxin-producing *Escherichia coli*. However, those strains of *E. coli* are also found in the digestive tract of healthy pigs, and the environmental conditions the piglets are exposed to before and at weaning play the most important role. Production results are strongly related to both the degree of segregated rearing systems and the level of hygiene. In herds rearing weaners on deep-litter bedding, both segregation and degree of hygiene are better, and the use of antibiotic three to four times lower than in herds with pigs in traditional post-weaning pens with solid **flooring**. Slatted flooring in the dunging area can lead to better pen hygiene, a lower infection pressure and lower **mortality** and **morbidity**,

P.636

in comparison with solid flooring. Pens with fully slatted floors do have potentially better hygiene, but this type of flooring can also be harsh on piglets' hooves and limbs. An increased risk of injury from flooring can result in an increased risk of infection.

In terms of **space** allowance in relation to **disease**, 0.25m² per pig at post-weaning stage (between 10 and 25 kg live weight) is a best compromise regarding health maintenance and production criteria. From epidemiological studies, a progressive increasing risk of disease has been found when the number of pigs per pen, stocking rate and space at the feeder are more than 13 pigs, <0.30m² per pig and <7 cm, respectively. At the farm level, the factors involved are not independent. Certain housing systems tend to induce certain practices. Hence large pens are associated with more mixing of piglets from different litters at weaning.

Another important aspect of the weaning environment is **enrichment**. Fully slatted systems with no obvious manipulable material for the piglets are associated with unwanted behaviours such as aggression and pen-mate manipulation (e.g. **belly nosing**, **tail-biting**). Straw in particular can reduce aggression and promote **play** behaviour, and reduce bellynosing.

Weaner calves

Natural weaning in **cattle** occurs when the calf is around 10-12 months of age. Generally, beef calves remain with their mothers until weaning at approximately 5-9 months of age. Veal and dairy calves, however, are separated from their mothers soon after birth and weaned around 6-8 weeks of age. Veal and dairy calves continue to be fed a liquid diet of either milk or milk replacer. Dairy calves undergo weaning at 1-3 months of age, whereas veal calves, especially those used for 'white' veal production, continue on a liquid-only diet with minimal roughage up to slaughter at between 5 and 7 months. Following separation, dairy and veal calves are often housed individually. In the USA, veal calves may still be reared individually in crates, which may be too small to allow the calf to turn round. Dairy calves are often reared individually in hutches with small runs, which allow basic body movements but not free locomotion and restricted social contact. In the EU, individual housing for calves older than 8 weeks of age is banned, and thus **group** housing is the norm. Group housing is becoming increasingly popular in the USA as well. The major advantages of individual housing are that of reduced disease transmission and ease of individual observation and treatment. However, calves are denied social contact.

The effects of individual versus group housing have undergone a fair amount of research, but direct comparison is often difficult as studies often vary a number of factors between treatments. With veal and dairy calves, studies have shown that mortality may be higher in group housing and the incidence of respiratory disease may be greater. However, difficulties in interpretation arise due to confounding effects of prior transportation. Group housing has no effect on likelihood of coliform, Salmonella or Cryptosporidium infection, but group housing may increase the risk of Johne's disease. More problems are found if group size is larger than 6-8 animals.

Behaviourally, individual housing does not allow calves to show many elements of their normal behavioural repertoire. Ordinarily, group-housed calves may spend around 2% of time engaged in **social behaviour**. Individually housed animals vocalize more and will work for social contact, and thus social behaviour must be seen as having some degree of importance to the calf. Individual housing may also have short-term effects on the calf's increased fearfulness when introduced to unfamiliar animals. The biggest restriction that individual housing places on the calf is its ability to carry out its full locomotory repertoire, and crates may also prevent certain postures that the calf would normally adopt. The main

behavioural disadvantage of group housing is the increases seen in **cross-suckling** - where calves will attempt to suck on pen-mates. This behaviour is greatly influenced by the method of milk presentation during this phase of life. If milk is delivered such that it is sucked from a teat, then cross-sucking incidence is greatly reduced, relative to bucket-fed calves.

Weaning ages for dairy and beef cattle differ considerably. Beef cattle are often left with their mothers on pasture-based systems until they are abruptly weaned anywhere between 5 and 9 months of age. Alternatives to this abrupt, complete separation are either to practise fenceline separation that allows the calf some social contact with the cow, or to attach a device to the calf that prevents the calf from suckling from the udder. Both these methods appear to reduce the calf's stress responses when the cow is finally removed. After weaning, many beef calves are transported to a **feedlot**. These are often open pens with dirt, concrete or slatted floors and a feed bunk. The range in sizes varies greatly, but it is not uncommon in the USA to have hundreds of animals within each pen. At this time, feedlot cattle are often subject to long-distance **transport**, mixing with unfamiliar animals and sudden change to a grain-fed diet to maximize growth. Unsurprisingly, mortality can occur and a number of health issues become apparent, such as increased respiratory disease, bacterial and protozoal infections, acidosis, **bloat** and liver abscesses. Without shelter, cattle may also be subject to both **heat** and **cold stress**.

For dairy cattle, abrupt weaning often occurs between 1 and 3 months of age, although separation has already occurred. Nevertheless, weaning is often accompanied by signs of obvious distress, with increased **vocalizations** and decreased growth. Initially, calves are weaned on to a grain-based diet, and they must undergo a further change on to a forage-based diet at a later date. Weaned dairy heifers are usually kept in groups and most have access to outside areas for at least part of the year. Obvious factors that will impact the welfare of these individuals are such things as group size, space allowance and bedding availability. However, the area of heifer housing has been somewhat neglected research-wise.

Weaner lambs

Natural weaning in sheep occurs when the lamb is around 5-6 months of age, and usually corresponds to the time that the ewe is coming into **oestrus** for the next breeding cycle. The ewe-lamb **bonding** is particularly strong during the first month, but there is evidence that it weakens over time and, by 12 months of age, relationships with peers appear to be more important. Artificial weaning in commercial production will depend on whether the flock is a meat production flock or a dairy flock. With a typical meat flock, weaning will occur at 2-3 months of age and the lamb will stay on the ewe for this time. With a dairy

P.637

flock, as with dairy cattle, maternal separation may occur immediately after **parturition** (1-4 days). If not occurring then, disruption of the ewe-lamb bond during the first month appears to be particularly stressful for both parties, and the lamb usually remains on the ewe until around 4 weeks of age.

Lambs from dairy ewes will therefore undergo a period of artificial rearing, during which time they will be group-housed with other lambs of the same age and fed milk replacer from a bucket. These lambs appear to shift their social relationships towards pen-mates and can benefit from **gentling** from a **stockperson**. As well as the social aspect, artificial rearing also affects feeding and growth rates. Allowing the lambs to have a mix of bucket-fed maternal milk and milk replacer counteracts some of the negative effects of replacer-only diets, improving growth, cellular immunity and behavioural responses to **open-field tests**. However, growth remains below that of lambs reared on the ewe. Gradual separation of lambs from dairy ewes has a larger negative impact than abrupt separation. Artificial rearing of lambs can also be associated with behavioural disturbances, such as redirected sucking on pen-mates and other non-food substrates, suggesting that these systems do not meet all the **behavioural needs** of young lambs.

For meat lambs and dairy lambs, weaning is usually carried out at 3 months. For meat lambs that have stayed with the ewe for this period, the stress of weaning and maternal separation is apparent. Separation causes increases in stress hormone concentrations, increases in activity, high vocalization rates and disruption of **circadian rhythms** of activity. Although lambs can be successfully switched to solid food by 1 month of age, even at 3 months of age the lamb usually has a period of reduced growth as the rumen is not fully matured. As with piglets, susceptibility to disease increases through impaired immune responses. Gradual separation, or allowing the lamb to remain with the ewe although prevented from suckling, appears more stressful for the lamb than abrupt separation. At 3 months, weaning may also disrupt social structure. After separation from the ewe, lambs re-associate in temporary groups, and an increase in pair association between twins is observed. It may take a year before full flocking behaviour is attained. Rearing of lambs in single-sex groups can also impact sexual behaviour, particularly of males.

Weaning

Weaning is defined as a process of permanent deprivation of nursing milk from the mammary gland of the mother (called udder for most animals) or any other artificial source of milk. Nursing animals rely on maternal milk for physical, cognitive and emotional formation, which provides the framework for proper development. Natural weaning happens slowly as the young animal is gradually introduced to adult-like solid feed, hence adjusting the digestive tract to the new diet. The solid feed should complement and/or compensate for nutrients, until then provided to the offspring through the maternal milk, for successful growth and development. An animal (or infant) is considered to be completely weaned when it no longer receives milk as part of its diet, hence relying solely on solid feeding for nourishment.

The age at which natural weaning occurs is evolutionarily species-specific. According to the literature, the time span during which an animal should stay **nursing** on its dam can be correlated to several factors. One of the assumptions is that weaning in mammals should happen when the offspring reach triple or quadruple that of their birth weight or one-third of adult weight. Another parameter relates to **gestation** length: the age at which weaning occurs is proportionally correlated with gestation length, but this correlation may be significantly affected by the adult size of the animal. For instance, small primates nurse for a period shorter than the gestation length, whereas large-primate nursing time exceeds their gestation period. Also, dental (or tusk) eruption has been described as a potential threshold for terminating nursing in some species (e.g. primates, **elephants**). Naturally, weaning age may be anticipated as a consequence of a decrease in the availability of essential **resources**, such as food and water, thus reducing and terminating maternal milk production.

Most animals living in their natural habitats (e.g. wild animals) tend still to wean their offspring gradually and at their natural time. However, this scenario is not commonly, if ever, seen in domestic species mostly subjected to animal production practices. In species such as swine, for instance, artificial (or enforced) weaning is a common practice and usually occurs abruptly, and is accompanied by complete separation from the dam. Additionally, it generally takes place several months prior to the biological age of weaning. For instance, the natural age for **pigs** to wean can range from 8 to 12 weeks but can happen up to 17 weeks of age (see Table W.1).

In swine production, pigs are artificially weaned at an average of 21 days of age and almost universally at a range of between 2 and 6 weeks of age. Dairy calves are separated from their dams soon after birth, ranging from 1 to 4 days of age, and fed with milk supplement, while they would naturally be weaned from their mother at around 12 months of age. Beef calves are usually weaned between 6 and 8 months of age. This implies that the still-nursing animals are taken away from their dams and are subsequently reared alone or with other artificially weaned animals.

The constraints dictated by the **intensification of animal production** systems have caused dramatic changes to the weaning age of several domestic species. This occurs because agricultural production has some important advantages with weaning animals earlier than their natural age. One advantage is the early control of diseases. An example of this is called 'all-in/all-out' management - a common practice in swine production. This practice involves removing, at the same time, all piglets from their dams and placing them in another separated, sanitized facility (nursery), eliminating pathogen exposure from the sow and older pigs. Piglets, when early-weaned

at around 2 weeks of age, are still under the immunological protection of maternal antibodies transferred in the colostral

milk (see: Colostrum). However, to be effective, it is extremely important that newly weaned animals are housed in an uncontaminated environment for efficient **disease** control.

Table W.1. Age ranges (weeks) for natural and artificial weaning for a range of animal species.		
Species	Natural weaning age (range)	Artificial weaning age (range)
Primates	52-78	13-26
Swine	8-17	2-4
Rats	4-5	3
Dairy cattle	43-52	26-35 ^a
Beef cattle	43-52	26-35
Sheep	18-23	9-13
Horses	52	18-26
Cats	8-12	5-6
Dogs	10	3-10
^a Permanently separated from the dam at 1-4 days postpartum.		

Artificial weaning also results in a more rapid return of the female to an active reproductive state. The separation of the offspring from the mother triggers the female hormonally to return to an active reproductive cycle, thus improving its reproductive efficiency (see: **Reproduction**). Maximizing the female's reproductive rate results in reduction of financial investments and higher profits due to a greater number of offspring produced in a shorter period of time. However, this idea is contradictory for some species (e.g. rhesus **monkey**, beef **cattle**), where non-interference in the natural weaning process may instead inhibit maternal reproductive system, by avoiding the inherent psychological **stress** associated with maternal-offspring separation. Permanent mother-infant separation prior to natural weaning is also a common husbandry practice in monkey-breeding colonies.

A better understanding of the nutritional needs of young animals has allowed improvement in feed quality and composition and nutritional management practices. Nowadays, diets are formulated to substitute all nutrients ingested from the milk and in fact taste similar to the maternal milk, thereby increasing palatability. Complex diet formulations favour higher consumption and thus better weight gain and growth rates of young animals, enhancing survivability. The earlier an animal is weaned, the greater are its nutritional requirements and more costly is the feeding programme. When abruptly performed, weaning is marked by weight loss and transitorily reduced growth rate, due to lower feed intake and stress resulting from permanent maternal deprivation. **Abnormal** behaviours are also observed in several animal species subjected

to artificial weaning. These consequences may be more severe in animals weaned too young, and certainly are indicative of a poor welfare state.

Weaning - a stressful event

Weaning is a traumatic and stressful event that may be accompanied by several other **stressors** that, when summed, can affect the health and **well-being** of the weaned animal and, ultimately, its dam. Physical separation of a young animal from its mother, and in some cases from its siblings, is undoubtedly stressful for both parties. As an alternative and to reduce the negative impact of maternal separation, weaned animals may be placed in an adjacent area or in the proximity of their dam. This procedure facilitates weaning by permitting visual contact and exchange of calls between the animals. However, this procedure is not always feasible, depending on the animal species and production system under which animals are raised. Another option is the use of an anti-suckling device, commonly used in beef cattle to carry out a two-stage weaning method. This apparatus is first placed on the nostrils of the calves and prevents the animal from nursing while still being kept with the dam. This stage is then preceded by full physical separation of calves from cows, which can also experience distress post-separation.

Most animals when weaned undergo a transitory loss of weight and reduced growth, with some being more susceptible to transient diseases such as diarrhoea and mild respiratory disturbances. These effects can be caused by sudden change of diet from milk to solid feed or by simply subjecting animals to a different environment. All these factors are combined into neurophysiological stress, caused by the lack of maternal contact. In some species, permanent maternal separation is performed when the animal is still very young and its digestive system is not yet fully formed to process diets other than milk. An example of this scenario is the maternal-offspring separation in dairy calves that is performed when calves are at maximum of 4 days of age. Thus, supplementation with artificial milk coupled with solid diet is provided to allow the digestive tract gradually to adapt to a solid diet such as total mixed ration and hay. Dairy calves are fully weaned from milk supplementation at approximately 3-6 weeks depending on body weight/condition and when enough grain mix is being appropriately consumed.

There are also negative consequences for the mother when the offspring is separated from her. A sudden removal of a suckling offspring from its dam can cause milk to accumulate in the udder and the occurrence of **mastitis** (udder inflammation usually caused by bacterial infection). Maternal milk production peaks within days or weeks after giving birth, varying with species, as young animals increase their milk consumption. Milk production is then gradually decreased as young animals increase solid diet consumption. Additionally, behavioural changes can be observed in the dam such as increased number of calls in an attempt to communicate with

P.639

the offspring, more pacing or walking (restlessness) and reduced feed intake, indicating distress. In some cases, acute reduction of milk production is seen. In cattle, and most likely in other species also, the longer period the offspring spends in contact with the dam, the more intense are the behavioural responses of the dam immediately after separation and, in cattle, the presence of calves can positively affect the **health** and productivity of cows.

Usually, artificial weaning is accompanied by environmental changes, when weaned animals are transferred to other facilities or areas to be housed. Adequate ambient conditions, such as good air quality, light intensity and suitable environmental temperatures are vital requirements for young animals in order to minimize disease occurrence and allow proper growth. For animals housed in groups, overcrowding in the environment should be avoided (**see: Social stress**). Attention and care, by trained personnel, must be provided especially to animals weaned at very young ages.

The effects of early maternal separation have been extensively studied and shown to cause long-term psychophysiological effects on the **brain** and behaviour of animals. The process of maternal separation affects the individual's behaviour by eliminating the predictability and controllability provided by the maternal presence and its interaction with the offspring. Weaning has been associated with a range of abnormal behaviours and/or **stereotypies**, which are **repetitive behaviours** with no biological function, and are considered to be indicative of poor psychological well-being. These behaviours are more evident in artificially weaned animals and are suggestive of neurophysiological stress, therefore being of welfare concern.

Behavioural responses to and after weaning or maternal separation are at some levels, species specific. **Crib-biting** in foals has been described to be associated with concentrate feeding and has been shown to increase after weaning. Artificially weaned piglets perform abnormal behaviours, such as **belly nosing**, where the animal mimics nursing by nosing the abdominal region of another pen-mate. Young weaned pigs also show chewing behaviour towards the pen bars, which is indicative of stress. Behaviours such as nosing, chewing or sucking other animals resemble massaging the maternal udder

and are contradictorily discussed as to whether they are abnormal behaviours associated with feeding or linked to social interaction. Early-weaned pigs also show reduced capacity to learn a spatial task and have an impaired ability to recognize familiar animals. Monkeys that have been separated from their mothers at birth or within the first year of life and raised in part or total social **isolation** show self-directed stereotypic behaviours, such as self-sucking of digits or tail and self-clasping in the absence of a **conspecific**.

Dam and offspring, when abruptly and permanently separated from each other, endure a traumatic experience. Increased rates of **vocalization** have been observed in several species following maternal deprivation in both dams and offspring, as both use calls for identification. In cattle, the mother and her calf vocalize intensively and show restlessness for several days, accompanied by less time lying and eating post-separation. These behavioural responses are exacerbated in beef calves suddenly weaned, at approximately 6-8 months of age, compared with behaviours of animals subjected to the two-stage weaning process, which allows the calf to gradually wean and separate from the mother.

Aggressive behaviour is another factor enhanced by early artificial weaning and has been found in piglets following maternal deprivation. Rats maternally separated also become more aggressive and show depressive and anxiety-like behaviour that can be accompanied by fearful or escape behaviour. The occurrence of abnormal behaviours, increased **aggression** and cognitive deficits suggest that the stress of weaning, an early adverse experience, alters the development and function of both the neuroendocrine and **autonomic nervous system** of animals.

Negative early experiences, such as maternal separation in **rodents** and other species, have been associated with multiple alterations in the adult brain, and are correlated with specific behavioural phenotypes depending on the timing and nature of the event. Maternal deprivation, especially if performed very early in life, is likely to interfere with the proper development of both psychobiological and neuroendocrine regulatory mechanisms in the developing brain. The stress-associated effects may be severe when associated with transitory nutritional deficit resulting from sudden alteration in the diet composition. This last factor may contribute to an impairment of neuronal mechanisms caused, for instance, by amino acid deficiency.

Early weaning of piglets can provide a useful model for studying early maternal separation effects on behaviour and neuroendocrine mechanisms. Previous studies revealed that piglets, when weaned at up to 28 days, show abnormal behaviour and intensified aggression later in life. In addition, piglets subjected to early weaning show suppression of genes encoding proteins associated with the stress response in the brain. A large body of scientific evidence indicates an age-dependent sensitivity of brain pathways to stress hormones. In pigs, for instance, the first 3 weeks of age are considered critical 'windows' of brain plasticity to alter behaviour and brain development. Weaning or maternal separation alone is a highly stressful episode that results in the release of **corticosteroids**, such as cortisol, and an increase of their concentration in plasma and **urine**. Cortisol crosses the blood-brain barrier and affects several brain areas by binding to corticosteroid receptors. One of the primary outcomes of central **glucocorticoid** action is to mediate a negative feedback system that suppresses **hypothalamic-pituitary-adrenal (HPA) axis** activity when its levels are elevated. Therefore, at early brain developmental stages, the disruption of the glucocorticoid negative feedback system may compromise the developing brain and be accountable for some aspects of cognitive impairment and abnormal behaviours.

Brain areas with abundant levels of corticosteroid receptor binding sites can suffer disruption of their functions under stressful events, such as weaning, primarily during the **sensitive phase** of brain development. High concentrations of the hormone in these brain areas cause behavioural and cognitive deficits that may not be reversible. Hence, early environmental manipulations, primarily during the first weeks of age or during the critical stage of brain development, may result in permanent changes in the HPA axis function and cause lifelong changes in behavioural responses. Currently, cerebral changes caused by stressors such as weaning can be studied in detail with the help

P.640

of molecular biology techniques. These techniques can be used to characterize, for instance, changes in gene expression profile in various tissues following exposure to stress. Molecular biology techniques are viable approaches for examining underlying neuronal changes that may affect animal behaviour and welfare of animals. Thus, connecting neurophysiological changes to behavioural alterations in response to stressors may facilitate a better understanding of the mechanisms underlying neuronal and behavioural effects of stress in animals weaned early in life.

Weather - effects on behaviour

Climatic physiology of farm animals is well understood, because they will not thrive in environments that depart from their climatic optima. Thus cattle of temperate climates, whose core body temperature is 38.2°C, have a thermoneutral zone from about -20°C to +26°C (**see: Thermoregulation**). This zone is defined as the temperature range within which metabolic heat production is independent of air temperature. Below it, the animals must generate extra heat. Above it, their heat loss mechanisms based on evaporation (sweating, panting) become unable to cope and metabolic rate rises, raising body temperature and endangering the life of the animal. The yak can feed and move normally at air temperatures of -40°C, but at 13°C its respiration rate increases, and at 16°C its heart rate and body temperature rise. Yak require the annual mean temperature to be below 5°C, and the average in the hottest month must not exceed 13°C. The pig has a very narrow thermoneutral zone (+16°C to +24°C), and for this species careful climatic control in **housing** and outdoors is essential.

Responses to uncomfortable ambient temperatures can be either physiological or involuntary (shivering, increased respiratory rate, sweating, etc.) or cognitive (shelter- or **shadeseeeking behaviour**). Animals respond to rain, and to precipitation generally, by cognitive processes. Whether these behaviours are performed will depend on the strength of **motivation** to perform or continue other behaviours, such as grazing.

Weaving

Weaving is the lateral swaying of the head. It may include swaying of the rest of the body (notably the shoulders) and picking up the front, and sometimes the hind, legs. Also recognized in exotic species, notably **elephants** and **bears**,

weaving is a common **ethopathy** in **horses**. It usually occurs over the stable door or in the face of some other barrier. As with other **stereotypies**, weaving may develop over time (e.g. it may change from a stationary head-swing to a side-to-side pacing). More than one stereotypic behaviour may be performed by an individual horse, e.g. a weaver may also be seen **stall-walking** on occasions. But the risk of locomotor versus oral stereotypic behaviours seem to be largely independent within an individual.

Concern for the **welfare** of weavers relates to the effects of excessive wear and tear on the hooves and the musculoskeletal system. Weaving may have a long-term effect on the animal's ability to learn; stereotypic horses have been reported to persist in non-rewarding activities longer than control horses (Hausberger *et al.*, 2007; Hemmings *et al.*, 2007). Weavers may also show altered time budgeting that represents a shift toward stereotyping at the expense of resting and feeding, an outcome that may result in a failure to thrive. This is one of the chief reasons for weaving being an unwelcome behaviour that must be reported at auction in some countries.

Weaving is reported more in Thoroughbreds ($3.25\% \pm 3.23$) than in other breeds, but it is unclear whether this reflects their **breeding** or environment, as gallopers are managed more intensively than any other equine athletes. It tends to arise at a median age of 60 weeks (i.e. after youngstock have been sold from the stud to new homes) and so does not appear to be related to **weaning** so much as to environmental and social disturbances at the time of dispersal. Along with other locomotory stereotypies, it is commonly seen in stabled horses before feeding or other arousing events, such as the arrival or departure of **conspecifics**. So it seems unlikely that weavers are subject to understimulation (or what might be labelled '**boredom**'), but rather that they have a thwarted **motivation** to move, e.g. to be with other members of the group or to reach food (**see also: Frustration**). Weaving may either be the expression of an unusual form of species-typical anticipatory behaviour and/or a learned response to a desirable outcome, such as leaving confinement.

Although reported as both more and less prevalent in standing stalls than in loose boxes, weaving is observed in pasture only when horses have encountered a barrier. If being in a stable is frustrating for a horse, it is possible that the lack of free exercise plays a role in the motivation to weave. However, the relationship between exercise routine and stereotypic behaviour is unclear. Exercise routine has not been identified as a risk factor in epidemiological studies and there

P.641

is little evidence that exercise has a consistent effect on the incidence of stereotypic behaviour in the stable. However, stimuli that signify turning out (to pasture) often act as catalysts for episodes of locomotory stereotypic behaviours.

When compared with the traditional solid-sided loose box, the provision of partitions that permit close tactile and visual contact with neighbouring horses reduces weaving. For example, in short-term studies, weaving was not observed when horses could socially interact with their neighbours on all four sides of their enclosure (Cooper *et al.*, 2000). This adds weight to the suggestion that weaving can be regarded as a frustrated escape response.

Found in approximately 70% of UK establishments, antiweaving bars, V-shaped apertures through which horses can put their heads and necks while limiting lateral movement, are the most common prophylactic for, or response to, weaving. Other attempts to prevent or interrupt weaving include fixing an upright bar or suspending a heavy object to occupy the space above the door, or completely preventing the horse from putting its head over the stable door. In response to all of these physical measures, most weavers simply move to an area within the box and weave without having their head and neck over the door. The merits of such physical impediments to stereotyped locomotion are spurious, since they probably increase affected horses' frustration with the environment by reducing the utility of the space provided.

Modifying cues that precede feeding or feeding times may reduce pre-feeding weaving but not post-feeding stereotypic behaviour. This, and the involvement of certain stimuli that reliably precipitate episodes of weaving, suggest that the role of learning in the emergence of stereotypies can be significant. So, while changing the husbandry routines may be an effective treatment of weaving, it is unlikely to be permanent because affected horses will most probably learn new associations that predict feeding in novel routines. Such changes would have to be continual to maintain their novelty value to avoid the behaviour returning to its original level. Crucially, however, flux in routine is considered harmful to horses, not least in terms of gastrointestinal **health**.

Exercise may help to reduce time spent weaving by causing fatigue and therefore prompting rest, which is an appropriate activity for stabled horses. Additionally, a practical measure may be to provide stabled horses with mirrors. In both short-term and long-term studies, mirrors have a similar effect to social contact, although it is unclear whether horses are simply distracted by reflected visual stimuli or whether they regard the image as another horse.

At the time of its emergence, weaving may be seen as a sign of frustration and possibly an indicator of compromised welfare. The extent to which a horse that is currently weaving can be used as an indicator of compromised welfare is

contentious. Many authors highlight the importance of the process of **emancipation** in liberating stereotypic behaviours from their initiating causes and argue that mature stereotypies may have lost any putative role in ameliorating distress. One reason for this being contentious relates to our poor understanding of the neural mechanisms that might reinforce weaving. For example, the role of **endorphins** as an intrinsic reward for weaving remains equivocal since **opioid** antagonists have been shown to both decrease and increase weaving.

Husbandry systems that facilitate social housing and therefore, by implication, are associated with reduced emergence of weaving are becoming increasingly popular, even though they may remain unattractive to some owners because they may permit undesirable social interactions (e.g. biting and bite threats) and the spread of contagions.

Weight gain

Weight gain is the increase in an individual's weight over a given amount of time. In the farm animal industries, weight gain is often measured in terms of average daily gain (ADG) in grams (g) or kilograms (kg) per day and is used as an indicator of how well an animal is growing in a given husbandry system. It can be combined with other parameters for **welfare** assessment. However, as with other parameters, it should not be used in isolation, and fast and efficient growth does not necessarily indicate good welfare. Its importance as a measure somewhat depends on the purpose for which the animal is being kept. For **companion animals**, the ideal is for the animal to grow normally, with normal weight gain until it reaches its final mature body size and thereafter to maintain its weight within a normal range for the remainder of its natural lifespan. These goals are similar for **zoo animals**. For **laboratory animals**, depending on the species and use to which they are put, they may or may not have a truncated lifespan and thus may or may not reach mature body size. However, the goal again would be to achieve normal weight gain up to maturity, then maintenance.

For **farmed animals** there are different management approaches to weight gain, depending on whether the animal is to be part of the **breeding** flock or herd or to be reared for meat production. For a breeding animal, growth and maturation are managed to maximize and prolong reproductive life. Often, this means controlling weight gain below that of the animal's maximal potential and then reaching a plateau of maintenance, but ensuring sufficient nutrition to support growth of the offspring during uterine development and subsequent **lactation** (for mammals) or maximize **egg production**, fertility and offspring viability (for poultry). For an animal being reared for meat, the aim is to get that animal to gain weight at its full potential - i.e. to grow maximally for minimal input and to reach **slaughter** weight in the shortest time possible.

Generally, the amount of weight that an individual will gain will depend on the relationship between the total amount of energy taken in and the total amount of energy expended.

P.642

Each animal has its own basal energy expenditure - that is the amount of energy required to maintain the body's normal basal metabolic activity, i.e. to keep the heart beating, sustain breathing, repair tissues and keep the **brain** and nerves functioning. Superimposed upon this are extra energy requirements needed for growth (if applicable), **thermoregulation**

and carrying out a normal behavioural repertoire. Also, if the animal is under **stress**, extra energy is required to meet the subsequent metabolic increases, such as increased **heart rate** and respiration rate, increased **locomotion**, etc.:

- If energy in exceeds energy expended, then the animal will gain weight.
- If energy in equals energy expended, the animal's weight will be static.
- If energy in is less than energy expended, then the animal will lose weight.

For breeding animals, growth, and thus weight gain, is usually controlled so that the different systems within the animal's body develop at a similar rate.

Due to genetic selection, many animals have the potential to grow extremely fast, and it is not uncommon for growth in the muscular system to outpace growth of the skeletal system. Rapidly growing animals such as some horses, pigs, broiler chickens and certain breeds of dog are known to have an increased incidence of leg weakness and bone diseases such as osteochondrosis (**see: Lameness**). In order to maximize reproductive longevity, growth is controlled so that the breeding animal has the musculoskeletal foundation to support reproductive function. This is often achieved by not allowing the animal to have *ad libitum* access to feed, but ensuring that daily energy intake remains above energy expenditure, thereby allowing limited growth. Once the animal has reached what is considered an 'adult' size and weight, feed intake may be reduced even further, so that the animal is theoretically obtaining levels that allow maintenance of body weight and support reproductive function. Again, this is achieved by restricting feed intake.

Monogastric species, such as breeding sows and broiler breeders, are often fed a single meal of high-energy concentrate diet, which can be consumed in a relatively short period of time, when they would often spend a great amount of their daily **time budget** engaged in foraging for a relatively low-energy diet. As a consequence, these animals are usually in a state of chronic **hunger**, which can impact the animal's physiology, behaviour and welfare. Also, some animals such as pigs and cattle have their commercial reproductive lifetime during the period in which they are actually still growing and have not yet reached full adult body size. It is therefore important that the amount of feed given takes growth into account, as well as stage of gestation or lactation, so that the animal does not enter a negative energy balance and start losing body condition.

For meat animal production, a more important figure than just weight gain is the ratio between weight gain and the amount of feed eaten - the gain:feed or G:F ratio. To maximize profit, the farmer is aiming for a high G:F ratio, meaning that the animal is making efficient use of the energy within the feed to put on weight. For example, it is more cost effective for a pig to grow 500 g/day by eating 800 g/day of food than to grow 510 g/day but eat 900 g/day of food. For the first pig, the G:F is 0.625, but for the second pig it is only 0.567. However, the financial benefit of greater feed efficiency does also need to be balanced against the costs associated with the extra time taken to reach slaughter weight.

Typical or expected weight gains are available for many domestic species. Although meeting the expected weight gains cannot be taken as an indicator of good welfare by itself, falling below expected weight gains can be an indicator of a welfare challenge. The most common causes of an animal failing to thrive are clinical or subclinical **disease**, inadequate access to feed or inadequate thermal environment. Many diseases may cause lethargy and anorexia (loss of appetite), meaning that the animal may not get up and feed. In groups of animals with poorly designed, competitive feeding systems, subordinate animals may fail to gain access to their allotted feed allowance and thus fail to meet their nutritional demands. Animals being housed outside their thermoneutral zone may either expend more energy maintaining body temperature if it is too cold or may become anorexic if it becomes too hot. In both cases, the energy balance is disrupted and weight gain will decrease.

Welfare

'Animal welfare' is a wide-ranging, and often value-laden, term that is used with somewhat different meanings by different people. It appears to have been first used by Major C. W. Hume, who was instrumental in founding the University of London Animal Welfare Society in 1926.

In non-technical assertions like 'securing the welfare of animals in our care is vital', the term 'welfare' refers to positive **well-being or quality of life**. In the technical literature on animal welfare, by contrast, it makes sense to speak about

welfare as a continuum running from negative to positive. In some contexts (e.g. in the notion of an animal welfare organization) the phrase 'animal welfare' carries the implication that we have an ethical obligation to treat animals well, or so as to meet certain minimum standards. However, many academics who study the living conditions of domestic and wild animals normally aim to use the term 'animal welfare' descriptively, simply to record the state in which an animal happens to be, without implying anything normative about the acceptability of the conditions in which the animal is kept. Also, in the academic study of animal welfare the term is normally used strictly to describe reactions of the individual animal being studied: welfare is a state of the animal. Here 'welfare' is used as a synonym of 'well-being' or 'quality of life', whereas in other, non-academic, contexts it can be used in statements about the environment in which the animals live.

The study of animal welfare is mainly undertaken as a part of natural science, building on disciplines such as **ethology**, **pain** - and stress-physiology and veterinary medicine (**See also: Measuring welfare**). However, important underpinnings of the study of animal welfare are philosophical in nature. Before studying animal welfare, we need a definition that clarifies what it is for an animal to be in conditions that are good for it and what it is for an animal to live a good life. From philosophical discussion of human well-being dating back to ancient Greece, two main views about the nature of

P.643

welfare emerge: (i) *perfectionism* (and associated *objectivist* views), according to which welfare is connected with *doing well*, e.g. by realizing important species-specific potentials; and (ii) *hedonism* (and allied *subjectivist* views), in which welfare is connected with *feeling well*, e.g. in the experience of pleasure and the avoidance of pain.

Often, advocates of these rather different views will arrive at similar conclusions about what is needed for an animal to live a good life. Positive **feelings** typically follow if an animal is allowed to pursue its natural goals, and pain or feelings of **frustration** may follow if an animal is thwarted in what it is naturally disposed to do. (Hens in battery cages appear to experience frustration when they are prevented from laying eggs in a nest.) However, it is not difficult to think of cases in which the two views might well diverge. Fighting to rise in the social **hierarchy** is natural in many animals and therefore positive from a perfectionist view. Nevertheless, a hedonist may consider it desirable to prevent painful fights - perhaps by limiting the aggression of male individuals through **castration**.

It is fair to say that subjectivist views presently dominate academic discussion of animal welfare. When Ian Duncan (1996) states that 'sentience, in other words feelings, is what animal welfare is all about', he is presenting a mainstream view. However, there are dissenting views: **Bernard Rollin** (1993) has observed: 'It is likely that the emerging social ethic for animals ... will demand from scientists data relevant to a much increased concept of welfare. Not only will welfare mean control of pain and suffering, it will also entail nurturing and fulfilment of the animals' natures, which I call **telos**.'

Again, in the following influential definition offered by Donald Broom (1986), the emphasis is on **coping**, or functioning - a basic form of perfection - rather than on feeling, although Broom himself acknowledges that **feelings** may be an important part of functioning:

The welfare of an individual is its state as regards its attempts to cope with its environment. Coping can sometimes be achieved with little effort and expenditure of resources, in which case the individual's welfare is satisfactory. Or it may fail to cope at all, in which case its welfare is obviously poor. Or, if the individual does cope with the conditions it encounters, this may be easy, with little expenditure of resources, or may be difficult taking much time and energy, in which case welfare is deemed to be poor.

Well-being can be measured in a variety of ways. Each method of measurement tends to suit some definitions of welfare better than others. Measures focusing on biological, psychological and social functioning are readily understood within a perfectionist framework. If, on the other hand, the researcher allows the animals to rank different outcomes (**see: Choice test; Economics of behaviour**), or concentrates on psychological well-being and **distress**, the measurements will make more sense in a hedonist (or, more broadly, subjectivist) framework. So researchers need to consider whether and how the data they record can be interpreted so as to say something about well-being in a specified sense. Measures of functioning often indicate little, directly at least, about pleasure, **suffering** and other subjective states of animals. It follows that the use of these measures within a subjectivist view of animal welfare requires critical discussion.

Welfare measurement

Ethical decision making (**see: Ethics**) and enforceable legislation derived from an interest in the physiological and psychological **well-being** of animals requires a set of well-defined measurements to assess animal **welfare** and criteria in order to distinguish between acceptable and unacceptable practices. However, the objective assessment of animal welfare is a topic of great debate due to the complexity and practical implications of the process. Measurement may focus on the physical and/or mental state of the animal, or its '**telos**'. Historically, many approaches to measuring animal welfare have emphasized the presence or absence of indicators of poor welfare (e.g. absence of **stress** or specific **aversive** situations such as **fear**, **hunger**, **injury**, etc., as espoused within four of the **five freedoms**); recently, however, greater attention has been paid to the potential to elucidate indicators of positive well-being, e.g. happiness, (see Désiré *et al.*, 2002) and the determination of the **needs of animals** (**see: Economics of behaviour**) and their provision (or not).

A hierarchy of needs has been proposed in relation to welfare. Some are life-sustaining, such as the need for food and water, others are necessary to maintain **health** and minimize the risk of ill health, such as the need for an environment that minimizes the risk from pathogens, while yet others are necessary for comfort, such as the need for appropriate bedding. Some may be more important than others, but all may be required if welfare is not to be seriously compromised (Hurnik and Lehman, 1985).

Initial problems when assessing animal welfare are its definition and the avoidance of **anthropomorphism** or **anthropocentrism** in the assessment process: the welfare and potential needs of an animal should be considered on the basis of the ecology and behaviour of each species and not on what we, as humans, believe is important. Indeed, the **behavioural ecology** of a species may be the starting point from which to set the criteria for measuring welfare. For example, good cage illumination is important for diurnal animals but may be detrimental for **nocturnal** species.

The measurement of welfare may focus on the individual or population. The latter may focus on factors like the incidence of disease, such as **mastitis** and **lameness** in the case of a dairy herd and the level of output from the unit (milk production, conception rate, etc.), and so be used to compare different

systems as well as different populations. It may or may not include specific personal measures from a sample of individuals.

Various welfare measurements of the individual have been proposed, focusing on either physiological or behavioural measures. Behavioural signs of welfare have frequently attracted more attention, perhaps because they are often more

conspicuous and their measurement is usually less invasive than physiological measurements. In relation to physiologically related measurements, attention is often focused on specific neurological, endocrinological and immunological parameters.

Behavioural approaches to the assessment of animal welfare include not only traditional approaches to **measuring behaviour** to quantify specific behaviours and determine the **ethogram** or **time budget** of individuals but also assessments of the variety and complexity of behaviours shown, and experimental approaches, e.g.: (i) consumer demand approaches to **preference testing** (see: **Economics of behaviour**) to allow the quantification of demand, which may be used to infer need (Mason *et al.*, 2001); and (ii) cognitive bias tests, which potentially assess emotional bias and may be used to infer subjective state (Harding *et al.*, 2004).

Another approach to the assessment of animal welfare focuses not on how animals are responding but, rather, on what is being provided; this might take the form of some kind of animal needs index (list of provisions potentially impacting on welfare), against which the management system can be rated. This approach is favoured within many regulatory frameworks, both legislative and voluntary, such as **farm assurance schemes**.

Historically, perhaps because of the traditional role of the veterinary profession in relation to the protection of animal welfare, much emphasis has been placed on measures of health to assess animal welfare; however, the importance of other measures is now universally recognized, with animal welfare scientists coming from almost every biological field, highlighting the fact that no single measure is sufficient to assess welfare but, rather, that welfare should be assessed using a range of measures and approaches. Different measures are required not only for different species, but possibly even for individuals in different circumstances. Because welfare itself cannot be measured directly (only inferred from the measures taken), a philosophical approach to assessing 'welfare' is to focus on addressing more precise questions relating to animal well-being, in order to identify whether there are any serious challenges to its well-being.

Different approaches tend to emphasize different measures. For example, the veterinary-medical approach suggests that animals should be in good physical health, free from disease and **injury** and not displaying any self-inflicting behaviour; the biological approach suggests that animals should breed successfully and should be able to rear their offspring; and the behavioural-ecological approach emphasizes that animals should live in physical and social environments resembling those of their wild **conspecifics**, where they can acquire and maintain the species-specific behavioural skills that they would need in their natural environment.

Well-being

Animal 'well-being' is often used as a synonym of animal 'welfare'. There is a small difference in usage, however. 'Welfare' is sometimes used to describe the conditions in which animals live and how they are cared for, whereas 'wellbeing' is used only to describe the resulting state in the animal.

(PS)

Whipping

Whipping refers to the use of the whip as an instrument of punishment or retribution. The most common form of whip is a long, thin, flexible instrument that tapers distally. It is designed to produce **pain** or discomfort and has a long history of use on both humans and animals, ostensibly for behaviour modification but, not infrequently, for retributive purposes. Its use on animals is often based on an anthropomorphic view of animal behaviour in which an animal is considered to be responsible for and cognizant of its actions or their consequences. There are various important **welfare** considerations surrounding the use of the whip in training animals.

When the whip is used in punishment, it is supposed to reduce the frequency of, and ultimately delete, a particular response. Critically, the **aversive** stimulus has to be contingent upon and contiguous with the behaviour targeted for removal. Delayed punishment has serious welfare implications and furthermore is frequently ineffective in removing a behaviour.

Even 'well-timed' punishment can be an impoverishing training tool. Haag *et al.* (1980) found that punishment in **horses** lowers their ability to offer a new behaviour in solving a problem. It can cause problems because it tells the animal what not to do, but *not what to do*. Punishment has the potential to desensitize an animal to the punishing **stimulus**

P.645

if the punishment intensity is not correct, and risks deleterious emotional changes that can interfere with attention and learning. Punishment can also foster unwelcome aversive associations with the person delivering it. All of these conditions apply to the misapplication of the whip.

The animal most commonly subjected to the whip is the domestic horse. Importantly, humane use of the whip can be an integral part of **horse training**. In this regard its irritant effect (through a tapping motion) may trigger certain desirable locomotory responses, but its application should cease at the immediate onset of the desired or targeted behaviour.

Use of the whip in horse racing is ubiquitous. Here it is largely intended to be used as a tool for training and eliciting acceleration. Unfortunately, it is largely misused in this context. However, the whip does motivate some horses (that are difficult to motivate by other means) to gallop faster. Its most humane use is to train it as a light acceleration **signal**. To

follow the laws of learning theory, the whip should be removed the moment the horse exhibits *any* acceleration. So, at best, humane training would demand a brief period of very mild whip use (closely spaced whip-taps until the onset of the targeted response) that is then rapidly replaced with a cue such as the jockey's body motion or squeezing leg signals to ultimately elicit the response. The use of the whip as an accelerating device in horse racing can be seen as abusive when it is excessive or applied for too long or to an animal that is unable to accelerate. 'Humane' whips have been developed that limit the force that can be applied. It should also be noted that the whip can be employed in all equestrian disciplines as a mild negatively reinforcing signal that can be as subtle as the tapping of human fingers. Therefore in itself the whip is not necessarily a severe punishing stimulus.

White noise

White noise is a sound that contains all frequencies at equal amplitudes. This can be represented by a flat power spectrum, or a uniform sound spectrogram with all frequencies represented equally. In this sense, white noise can be seen as analogous to white light, which contains all visible frequencies. In theory, white noise may extend across an infinite range of frequencies, although in practice this could never be produced, as it would require infinite power. More practically, the frequencies should be flat (that is to say represented equally) across the range audible to the listener. For humans this range is approximately 20 Hz to 20 kHz. Noise can also be 'coloured' by emphasizing certain frequencies to achieve 'red', 'pink', 'brown' noise and other variations. White and coloured noises can be useful to mask other sounds from the environment, such as sounds that might startle livestock. This noise is also sometimes used in experiments as a control **stimulus**. In this way, the effects of sounds that may be biologically meaningful (such as animal **vocalizations**) can be compared not only with silence but also with another sound equal in energy, and perhaps even in duration, rate and other features.

(DW)

Wild animals

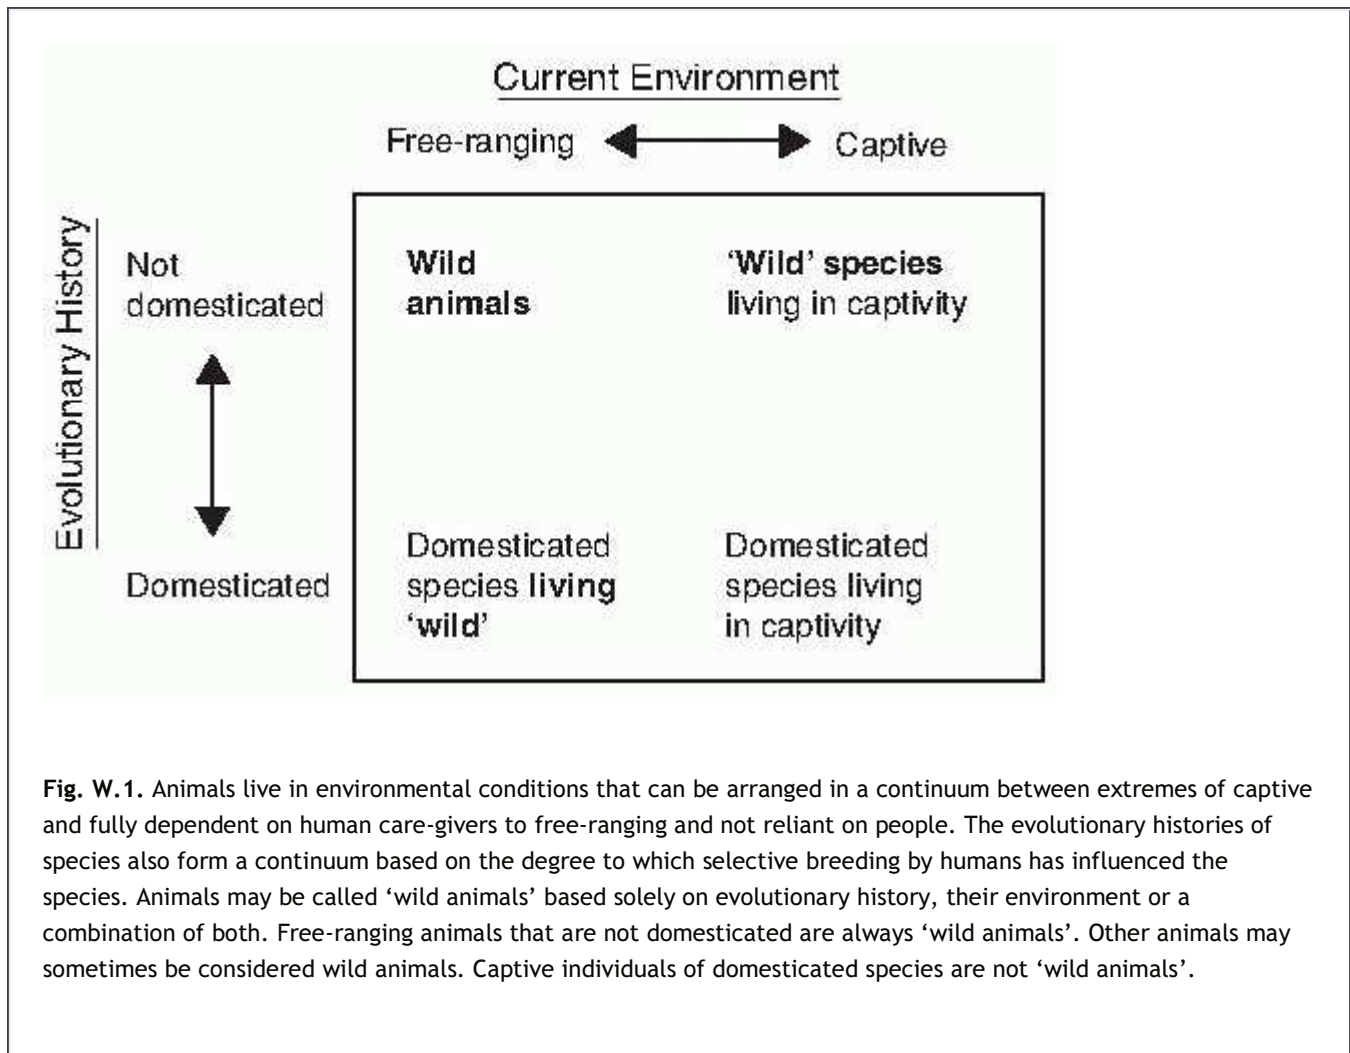

The label 'wild animals' can have legal implications and influence animal management and **conservation**. In identifying animals as 'wild', we may consider the evolutionary histories of species as well as the current environment, or living conditions, of individual animals or populations of animals, including their relationship to humans (see Fig. W.1).

Many animals around the world that are free-ranging and not domesticated group easily together as 'wild animals', and many captive domesticated animals, such as dairy cows or seeing-eye dogs, could be excluded from 'wild animals' without debate. However, free-ranging species that have undergone **domestication** and captive non-domesticated animals present greater challenges in labelling. How would we categorize domesticated or semi-domesticated animals that have free-ranging populations, such as horses or European honey bees in North America? How would we describe captive or semi-free-ranging individuals of 'exotic' species, such as animals in zoos or sanctuaries, dolphins trained to assist military operations or 'sea monkeys' in a child's aquarium?

In the *Origin of Species*, Darwin (1859) uses 'organic beings in a state of nature' to refer to non-domesticated plants and animals arising through **evolution** by natural **selection**. Darwin sets up this apparent dichotomy between domesticated and non-domesticated animals but makes it clear that animals cannot be cleanly separated into these two simple groups; he explains that evolutionary history yields a continuum of variation rather than a strict dichotomy. 'Wild animals', as a faunal -oriented equivalent to 'organic beings in a state of nature', is a convenient and useful term to represent the opposite of 'domesticated'. Some legal statutes that regulate or prohibit the keeping of 'dangerous wild animals' in private homes use the domestic-non-domestic dichotomy, defining 'wild animals' as species 'other than domestic' ones. The

statutes may not directly discuss the evolution of wild animals, but the distinction between legally and illegally held

animals relies on whether the animal is a result of selective breeding for traits favourable to people or whether the species evolved only naturally, via natural selection.

Most animals in zoos and aquariums are also 'wild animals' based on the evolutionary histories of the species, but they may not be considered truly wild compared with their free-ranging **conspecifics**. The potential for captive animals to impact their species' evolutionary future is restricted by humans and, in captivity, they may exhibit certain behaviours not seen in nature and may not exhibit the full range of their species' natural behaviours. Drawing distinctions between captive wild animals and animals living in nature, or ranking their relative levels of 'wildness', can be important for achieving conservation goals. For example, **captive breeding** and **reintroduction programmes** may characterize the behaviour of a species in the wild, examining free-ranging wild animals to establish standards by which to measure the behaviour of captive reintroduction candidates. A measure of success for a programme might be how 'wild' released individuals behave relative to the original 'wild' population.

Arranging animals according to evolutionary history and current environment might not yield groups that are meaningful or sufficiently distinct for management strategies for ecosystems or protected lands. Identifying all free-ranging, non-domesticated species as 'wild animals' encompasses non-native animal species into this group, but natural resource management plans and conservation efforts generally devise different strategies for native species than for non-native species. Thus, a species' historical presence might be part of a resource-based definition of 'wild animals' or an important characteristic for subdividing species of 'wild animals' for management planning. A recently proposed 'rewilding' strategy for ecological restoration of North America suggests intentionally introducing non-native or feral species as proxies for fauna that have gone extinct. For this strategy, ecological function is the primary consideration in identifying rewilding candidate species.

The management of non-native species and free-ranging, domesticated (i.e. **feral**) animals has long been highly controversial, drawing proponents for protection and for removal. The US Wild Free-roaming Horse and Burro Act of 1971 protected wild horses, a feral species, as an added element of animal diversity and as symbols of the 'pioneer spirit of the

West', but controversy over the presence of horses on public lands continues. Similar controversy has surrounded dingoes in Australia, with arguments both for their preservation as wild animals and for their removal as potential livestock predators. Taxonomic classification of dingoes as a subspecies of dogs or a subspecies of wolves does not alter dingo behaviour or **ecology**, but it may shift the debate between the management and control of a domesticated species and strategies for conservation and coexistence with a wild species of carnivore.

Most large carnivore species range widely and come into conflict with people. Development activities increasingly fragment the landscapes that can meet the large-area requirements of carnivores and other wide-ranging species, restricting their movements or funnelling wild animals into sub-optimal habitats. Humans are therefore altering the spectrum of environmental conditions, inadvertently and intentionally fencing wild animals inside smaller areas and more highly altered and human-dominated landscapes. These changes blur the distinctions between captive and free-ranging conditions and alter the evolutionary outcomes of species, most dramatically in extinctions. Our perception and definition of 'wild animals', and our actions towards them, may shift as we alter these continua.

Wildlife management

Wildlife management is the process of deliberately affecting the future of wild species and their habitats through the deployment and manipulation of various **resources**, including human, financial, material and intellectual. Originally linked to **hunting wild animals** for consumption or display, it now encompasses many human attempts to protect, conserve, limit, enhance, recover, use or eradicate wildlife. The modern professional discipline of wildlife management requires the application of scientific and technical principles to wild populations and their habitats (especially mammals, birds and fish) in order to regulate such populations for economic, recreational or scientific purposes.

Frequently, wildlife management requires the intentional manipulation (or intentional non-manipulation) of habitat rather than of the particular species directly. This requires strategic planning, managing resources, deploying necessary human and financial assets and measuring results. It also includes researching species and their physiology, behaviour and **ecology**. But wildlife managers are not necessarily ecologists; they have different professional backgrounds, including biology, veterinary medicine, agronomy and forest engineering. Wildlife management includes creating and implementing laws that regulate the use of wildlife and the kinds or amount of wildlife that people can harvest. Wildlife management techniques are used to intervene directly into the species' life history, the habitats' carrying capacity and the human effect upon them. Strategic interventions of wildlife management include:

- habitat control or management, in order to favour or eliminate some species;
- culling, translocating or deterring wild species, in order to control any damage caused by them;
- culling infected wild species, in order to prevent transmission to livestock, humans or other wild species;
- predator control or management, in order to prevent damage to domestic species (livestock, pets and ornamental animals), other wild species and humans;
- providing supplemental water, in order to increase some species populations;

-
- providing supplemental food, in order to increase some species populations; and

- conducting census counts and behavioural and physiological studies, in order to acquire the knowledge necessary for pursuing these strategies.

Wildlife specialists collect such information and manage such populations to achieve a variety of recreational, economic, cultural and aesthetic benefits for people while ensuring the future of wildlife and their ecosystems. They can aim to increase, maintain or decrease a species population, or choose to leave the species alone.

Conservation biology is one kind of wildlife management that aims to maintain or increase species that have been negatively affected by human action. But wildlife management encompasses much more than conservation biology, such as exploitation for food or other products that contribute to human needs. Wildlife management is also concerned with the negative effects of wildlife on human assets, such as predators near livestock, birds at airports and rats where food is processed.

Sustainable use of wild species is another objective of wildlife management. In this case the aim is to provide economic benefits to local communities by harvesting products or by-products from wild animals without negatively affecting the viability of the targeted population or its environment. The use to be sustained can range from culling for food, to shearing, to recreational observation. Animal welfare concerns vary depending on the degree and kinds of use. Examples of such concerns, in consumptive and non-consumptive uses, are inhumane methods of culling that cause much suffering before death and constant harassment for photographs in some forms of **ecotourism**.

Wildlife control involves removing, scaring or culling wild animals from certain places. Control techniques range from non-lethal repellents and fertility control to lethal traps, chemicals and shooting. Wildlife managers regularly confront the need to destroy wild animals for various reasons, such as protecting **endangered species**, protecting public **health** and controlling the population of species considered pests. Concern for animal welfare calls for methods of **euthanasia** that are humane to the target species and not dangerous to non-target species. It is difficult to satisfy both conditions when little is known about the effectiveness and response to control methods (physical or chemical) on wild species. Many control methods thus confront strong opposition from animal welfare specialists, and criteria and recommendations for euthanasia and control in the wild are still highly controversial. Wildlife managers and veterinarians are addressing this issue: the American Society of Mammalogists and the American Veterinary Medicine Association, among others, have suggested criteria for euthanasia.

The wildlife manager's concern with animal welfare also applies to **captive breeding programmes**, **reintroduction** to native habitats, **translocation**, **zoos** and rehabilitation centres. Since wildlife requires moving freely, acquiring food and shelter, and interacting with the environment while subject only to pressures of natural selection, any form of **captivity** implies a potential animal welfare problem. Even as they employ temporary captivity for the purposes of rescue and conservation, wildlife managers should work to alleviate any human-induced stress and **suffering** caused by that captivity.

Wildlife management in general is related to ecology as the science of animal welfare is related to individual animal behaviour and physiology. Both disciplines are forms of professional expertise that intervene in animal life and therefore involve a serious ethical dimension (**see: Ethics**). Wildlife managers must employ the science of animal welfare if they are to improve the quality of captive animals' lives and prevent or alleviate anthropogenic harm to animals in the wild, besides the more known traditional priorities of this discipline (i.e. protection, conservation, environmental protection, sustainability, control and human **well-being**).

Wilson, Edward Osbourne (E.O.)

E.O. Wilson was born in Birmingham, Alabama on 10 June 1929, and is largely credited with the development of the theory of **sociobiology**, but is also a proponent of the **biophilia** hypothesis, a secular biological basis to **ethics** and **conservation**. In addition to his scientific work, he has written extensively for the popular press on his theories and discoveries.

(DSM)

Wind-sucking (aerophagia)

This term is used to describe two quite distinct conditions in the **horse**: a stereotypic behaviour and a behaviour dependent on a conformational fault of the perineum. Poorly distinguished from **crib-biting**, wind-sucking describes the stereotypic

engulfing of air by horses with (Australia) or without (UK) holding on to a fixed object. The fixed objects most commonly used include the feed trough (hence the term crib-biting) and the stable door. Other substrates include fence posts, railings, other horses and even the affected horse's own limbs. Horses often lick the substrate before using it. The neck is always flexed during the consummatory phase of the behaviour. In the past, it was commonly assumed that every grunt a wind-sucker made marked a bolus of air that was being swallowed. However, when wind-sucking/crib-biting horses were radiographed, it became clear that little if any air travels as far as the stomach. Instead, each grunt accompanies transient ballooning of the cranial third of the oesophagus with air, which then departs through the horse's open mouth. Significantly, no deglutition is involved and therefore the air is described as having been engulfed rather than swallowed. Aerophagia is considered a redundant term in the light of this discovery.

The question of why horses are often highly motivated to wind-suck remains, but several theories have been advanced. For example, it may be that, in holding on to fixed objects with their teeth and then arching their necks, horses generate saliva that acts to buffer gastric acidity. This is supported by evidence that foals crib-bite less when treated for gastric ulceration. Another possibility is that, in distending the cranial oesophagus, horses somehow stimulate the release of **endorphins**, as hinted at by studies showing that opioid antagonists transiently eliminate crib-biting.

Since it disturbs the normal equine time budget, wind-sucking can compromise a horse's ability to maintain condition

P.648

by occupying time that it would normally spend **feeding** and resting. It is a behaviour that must be declared prior to auction in some countries.

Wind-sucking, as a stereotypic behaviour, should not be confused with the acquired conformational fault of the perineum in mares that leads to pneumovagina (also known as wind-sucking; **see: Caslicks**).

Wire-gnawing

When placed in cages, laboratory **rodents** and **rabbits** often chew the wire bars of the cage or lid. This behaviour can rapidly become highly persistent and prevalent. In one study on mice, all 24 animals developed wire-gnawing between 20 and 30 days of age in one strain and before 40-50 days of age in another. It occupied 11% of the total activity, although large individual differences occurred. When wire-gnawing is prevented by placing the bars so close together that the nose cannot be pushed between them, mice show an initial increase in **corticosteroid** levels indicating an acute **stress** response; however, these levels return to pre-treatment baseline values within 3 days as the animals develop new behavioural habits. Prevention of wire-gnawing has no significant effects on chronic measures of both the sympathetic-adrenal-medullary system and the **hypothalamic-pituitary-adrenal (HPA)** axis, indicating that wire-gnawing does not reduce chronic stress and therefore is not a '**coping** strategy'. When reared in cages with two sets of bars, mice interact more with a set that provides a potential escape route than one that does not, possibly indicating that the motivation for wire-gnawing lies in prolonged attempts to escape. Environmental **enrichment** in the form of hay for rabbits, a **running wheel** for **hamsters** or cardboard tubes for mice have been shown significantly to reduce wire-gnawing.

(CS)

Wirkwelt

Derived from the German *wirken* meaning 'to act' and *welt* meaning 'world'. Defined by Jacob Von Uexküll (1934) in his **umwelt** theory, the **wirkwelt** is the operational world of an animal. The **wirkwelt** of an animal thus depends on its effectors and is composed of all its potential responses toward its environment. The interrelation between the **wirkwelt** and the **merkwelt** (i.e. the perceptual world) enables the animal to interact with its **umwelt**.

Wood-chewing

Wood-chewing (lignophagia) occurs naturally in a number of species, including some of the herbivores: for example, **deer** stripping bark from a tree. In mammals it can make up a small part of the feeding strategy and may only be observed under certain conditions. It is thought as occurring to supplement a nutritional requirement, possibly for more fibre in the diet, although the stripping of willow bark, which contains salicylic acid (aspirin), may be a form of **self-medication**.

Abnormal wood-chewing has commonly been reported in domestic **horses**, particularly when they are stabled for long periods and fed a high cereal-low forage type of ration, browsing including incidental wood-chewing is a normal behaviour in the donkey. However, the behaviour pattern is not exclusive to equids, as it has been observed in sheep in the form of slat-chewing when they are confined to metabolism crates and provided with little forage. In general, the wooden surface is grasped, stripped and then ingested. Damage can occur to any available wooden surfaces such as the top of the stable door and the walls. The chewing of wooden railings has also been observed in horses kept at pasture.

Wood-chewing has been described as an **abnormal** behaviour by some authors when it occurs repetitively and out of context. It has also been recognized as a behavioural problem by owners or keepers, particularly when the chewing occurs at their financial expense. Habitual wood-chewing can also be potentially harmful due to the risk of swallowing wood splinters.

In the horse it is important to distinguish between wood-chewing and **crib-biting**, another oral stereotypic behaviour, as in both cases a surface is grasped by the teeth, though ingestion of wood does not occur during crib-biting. Therefore, the impression of tooth marks from the incisors on wooden surfaces should not be taken as a definite sign of wood-chewing.

There is good evidence to suggest that feeding a ration high in cereal and low in fibre is implicated in the development of wood-chewing and that it may arise as a consequence of a strong motivation to forage, coupled with harmful changes in the pH of the gut. Measures such as painting surfaces with taste repellents or removing chewable surfaces from the stable should therefore be questioned on welfare grounds, as they act to curb the problem behaviour through prevention of the behaviour rather than addressing the cause or underlying motivation.

Wool-eating

Wool-eating is behaviour involving an animal (typically a **sheep**) eating its own wool or the wool of other individuals. The behaviour can result from either of two situations. First it can be a response to insect infestation, typically blowfly strike or sheep scab. By removing the wool the animal can use its mouth to scratch the site of infestation and help to alleviate some of the **pain**. In addition, any maggots or eggs in the wool will be removed from the animal. The second situation in which wool-eating occurs is when sheep are under stress from a lack of high-quality feed **resources**. It is a traditionally held belief that animals eat wool in order to supplement their diet with essential micronutrients, as wool contains trace elements. This situation typically occurs when livestock are overwintered

on poor-quality feeds. Akgul *et al.* (2000) showed that levels of most micronutrients were normal in affected animals, although levels of copper and zinc were lower than in unaffected animals, as were haemoglobin levels and the total protein value of blood serum.

This behaviour can be passed to animals in an affected **group** from those from a non-affected group when the groups are mixed. Thus, not only is wool-eating a sign of a problem within an individual, it could also be symptomatic of a problem within its group, even if the individual observed shows no malnutrition or insect infection. As either situation is a serious **welfare** and production problem, if wool-eating is observed in a flock the whole flock requires inspection and action to correct the problem.

X

Xenograft/xenotransplantation

Xenotransplantation is the transplantation of an organ, tissue (grafts) or cells from one species of animal to another (not to be confused with **transgenics**). The technique was developed to make up for the shortage of human donor organs for transplantation. Recently, xenotransplantation has been the subject of much research, but also concern, as transgenic pigs were developed whose organs would not be subject to the very rapid (hyperacute) rejection that would normally occur in the first few seconds after a blood supply from the recipient is connected to the transplanted organ. To date, despite their potential for saving human lives, no organ transplant procedures have become adopted as routine for fear of infection passing to humans from the donor species (xenozoonosis), as well as doubts that they will be successful for a variety of other reasons, e.g. physiological compatibility.

(DBM)

Xenopus

Species of *Xenopus* are fully aquatic **amphibians** occurring in Africa south of the Sahara. The best known is *Xenopus laevis*, employed intensively in laboratory research for over 70 years. Early work concerning physiology, biochemistry, embryology and endocrinology contributed significantly to understanding in these disciplines. Currently, this species is one of the most widely used laboratory **animals** in developmental, cell and molecular biology.

The common name 'African clawed toad' (or 'clawed frog') refers to the keratinized black claws on three of the toes. The terms 'toad' and 'frog' are used inconsistently for *Xenopus*, but these names do not have strict scientific relevance and *Xenopus* is actually distinct from both 'groups'. Its morphology is distinctive, with flattened body and limbs splayed laterally (see Fig. X.1); its streamlined shape, powerful legs and webbed feet contribute to specializations for life underwater. Relatives in the family Pipidae include species of *Pipa* (in South America) and *Hymenochirus* (in Africa). Fossils of extinct pipids occur in South America, Africa and the Middle East, indicating a wide distribution before the Atlantic opened up (about 90 million YBP). The earliest known fossils are from the Lower Cretaceous (120 million YBP).

There are 18 species of *Xenopus*. These have major genetic and evolutionary interest, forming a polyploid series with two lineages: one with 20 and 40 chromosomes, the other with 36, 72 and 108. The 20/40 chromosome group has a separate genus name, *Silurana*, as distinct from *Xenopus*, with multiples of 36 chromosomes. *Silurana tropicalis* is the only species retaining the ancestral diploid state ($2n = 20$); all other species evolved through allopolyploidization - hybridization between different species accompanied by genome duplication. *X. laevis*, with 36 chromosomes, is tetraploid and contains the genetic information of two (unknown) ancestral species. Six species are octoploid and two (*Xenopus ruwenzoriensis* and *Xenopus longipes*) are dodecaploid (108 chromosomes), containing six sets of genetic information. Such complexity is extremely rare among vertebrate animals, although it occurs in plants, including ferns.

The habitats of *Xenopus* include most types of water bodies in sub-Saharan Africa, especially the still waters of swamps, ponds and streams. *Xenopus* are less common, or absent, in rivers and lakes, especially those with well-established fish communities. The two species most frequently employed in laboratory research, *X. laevis* and *Xenopus tropicalis*, are ecologically distinct. *S. tropicalis* is limited to lowland tropical forest in West Africa, from Nigeria to Senegal. *X. laevis* is a generalist savannah species distributed from South Africa to Sudan, with a series of subspecies corresponding with latitudinal zones. Most research has been based on *Xenopus laevis laevis* from South Africa, but there is significant evolutionary divergence within this subspecies, corresponding with the winter rainfall area of the western Cape and the summer rainfall area further north. However, this should not confuse existing research findings, because supply of *X. l. laevis* to laboratories has been predominantly from the Cape.

Fig. X.1. *Xenopus laevis* in characteristic pose, partially hidden in a refuge, with forelimbs outstretched in readiness to capture prey organisms that may drift past in the water column or land on the water surface above. The hind legs have powerful musculature for rapid swimming and the foot has black claws on the innermost three digits. The eyes are directed upwards. The prominent bulges on the posterior dorsum are created by the large, inflated lungs in the body cavity. 'Stitches' are visible around the eyes and along the flanks: these are the lateral line organs sensitive to movement, vibrations and pressure changes. This subspecies, *X. l. victorianus* from East and Central Africa, has deep yellow pigmentation on the legs and a white belly; the dorsum is camouflaged with olive-brown pigments. Body length (from nose to vent) is about 60 mm.

P.652

The diet of *Xenopus* includes a wide variety of invertebrates. The prey range is distinct from that of other anurans because *Xenopus* feed underwater and are scavengers, detecting dead animals by **odour**. The tadpoles are filter feeders, exploiting plankton. Although normally fully aquatic, *Xenopus* can tolerate extreme conditions, including aestivation in dried-up ponds for over 6 months and survival for many months without food. *X. laevis* tolerates a wide temperature range, from 4 to 28°C, and can overwinter under ice in frozen ponds. However, physiological adjustment to this range requires gradual acclimation. The temperature optima of tropical forest species reflect their more uniform habitat conditions: e.g. 25-30°C for *S. tropicalis*.

Sensory perception, including vision and **olfaction**, shows dual adaptations for both air and water. In most amphibians, the lateral line system (present in tadpoles) disappears at metamorphosis; in *Xenopus*, the lateral line is well developed in adults and can detect changes in water pressure (depth), currents and vibrations. This provides a highly accurate system for locating unseen prey. *Xenopus* communicate by specialized **vocalizations**, maintain territories underwater and have dominant/subordinate **hierarchy**; they are capable of complex learning and long-term **memory**.

The skin of *Xenopus* produces a considerable diversity of secretions, including toxins that deter attackers, natural antibiotics protecting against infection (including 'magainins' that kill bacteria by perforating membranes) and a wide range of peptides that have pharmacological significance.

Export of *X. laevis* from South Africa for use in laboratories and the **pet** trade has led to establishment of introduced populations in many countries, including the USA, the UK, France, Italy, Portugal, Indonesia, Japan, Chile and Ascension Island.

Maintenance of *X. laevis* in laboratories began with its use in human pregnancy diagnosis based on the fact that hormones in urine of pregnant women trigger egg laying by female *Xenopus*. The current major application of *Xenopus* in molecular genetics exploits the large size and very active gene transcription of its eggs. Following micro-injection of DNA from animal

or plant cells into the oocyte, all stages in gene expression occur leading to translation into protein (of the foreign organism).

For maintenance in **captivity**, semi-natural conditions can be created in aquariums reflecting the habitat conditions of *Xenopus* in the wild, including dim illumination, refuges and minimal disturbance. This approach can be successful for long-term maintenance (with lifespan exceeding 20 years). In large-scale maintenance, *Xenopus* may adapt well to simplified environments, but some laboratories with demanding research protocols experience problems with oocyte quality that may be attributable to **stress**. Animals taken from the wild are caught as adults, after at least 3 years in natural habitats where they are **nocturnal**, secretive and accustomed to the security of cloudy water. Transfer to laboratories, where *Xenopus* experience clear, shallow water, illuminated from all sides, with frequent disturbance, may cause stress. Wild-caught animals may carry parasitic and microbial infections.

Ovarian condition varies depending on season and recent **breeding** history: *X. laevis* may spawn up to three times during spring/summer at the Cape, South Africa (September to February), so some females arriving in laboratories have gravid ovaries prepared for ovulation while others have depleted ovaries following natural spawning. Adult *X. laevis* collected during April-July (late autumn/winter at the Cape) may be taken from water at 10°C, unprepared for immediate spawning and experience shock when transferred to laboratory conditions. These problems are avoided with laboratory-raised animals. For intensive laboratory 'production', semi-automated aquariums provide environmental control, including water quality, and *X. laevis* can reach maturity in 6 months postmetamorphosis.

Research based on *Xenopus* has contributed to major advances in biomedical and fundamental science, and its use seems certain to increase in the future. It has been an anomaly that very demanding research techniques should be subject to the inherent variability of wild-caught animals. It is appropriate that future research should be based primarily on purposebred animals. This shift in practice will simultaneously resolve other issues concerning **ethics**, legal regulations, **disease** risks and behavioural stress associated with transfer of animals adapted to natural conditions into intensive laboratory maintenance.

Research on the welfare and parasitic infections of *Xenopus* has been supported most recently by grants BB/C506272/1 and BB/D523051/1 from BBSRC.

Z

Zoo

Zoo is an abbreviation of the term 'zoological garden' or 'zoological park', and is now the most commonly used term for a place where live, non-domestic animals are maintained in **captivity** for the purposes of display to the public. Zoos have existed since ancient times, the earliest known being those of the Egyptians (c.2500 BC), Chinese (c.1000 BC) and Greeks (c.500 BC). The first use of the term 'zoological garden' was in 1828, when the Zoological Society of London founded the London Zoological Gardens at Regent's Park; the shortened version of the name, London Zoo, was rapidly adopted.

They are many types of zoos but, according to the World Association of Zoos and Aquariums (WAZA), the key factors that all zoos have in common are: (i) they possess and manage collections that primarily consist of wild (non-domesticated) animals, of one or more species, that are housed so that they are easier to see and to study than in nature; and (ii) they display at least a portion of this collection to the public for at least a significant part of the year, if not throughout the year.

In Europe (that is member states of the European Union (EU)), zoos are defined legally as 'all permanent establishments where live animals are kept, with a view to public display for seven days per year or more, with the exception of circuses and pet shops' (Council of the European Union, 1999). EU member states are allowed to exempt certain establishments from this definition based on the number or species of animals held. Most states have exempted those only keeping domesticated species. For instance, in the UK a zoo is legally defined as 'an establishment where wild animals are kept for exhibition ... to which members of the public have access, with or without charge for admission...' (Zoo Licensing Act 1981), and **wild animals** are defined as non-domesticated species.

Although the term 'zoo' includes all establishments exhibiting wild animals to the public, in popular thinking zoos are often thought of as distinct from wildlife parks or safari parks. This distinction is usually based on the types of enclosure in which the animals are kept, with zoos being regarded as having traditional cages and wildlife parks featuring much larger and more natural enclosures. However, this distinction is totally arbitrary because there is no clear cut-off point where a zoo becomes a wildlife park, and an enormous range of enclosure styles and sizes can be present within a single establishment. Aquariums also fall into the legal definition of zoo in most countries, as do specialist **marine mammal** parks. There are also many other types of zoos, such as animal theme parks in which visitors are entertained by various rides and roller coasters in addition to live animal exhibits, as exemplified by Disney's Animal Kingdom in Florida, USA, opened in 1998. Wildlife sanctuaries that care for rescued animals, with or without an intention to rehabilitate them back into the wild, are also legally zoos if they admit the public to view the animals.

The first known zoos were those of the ancient Egyptians; Queen Hatshepsut organized the earliest recorded animalcollecting expedition (c.1500 BC) and Ptolemy II founded the largest ever zoo at the time in Alexandria (c.280 BC). Even by today's standards this was an enormous zoo and included 96 elephants and the first known captive polar bear! Zoos have been created by many cultures all over the world including the Chinese (e.g. Empress Tanki's marble house of deer, c. 1150 BC) and the Aztecs of Mexico (Montezuma II in the 16th century had a zoo so large it reportedly required 300 staff). Not many other forms of public entertainment can claim to have been so popular throughout the world and to have persisted for so long - at least 5000 years. This universality and longevity demonstrates how powerful humans' desire to interact with wild animals must be. This desire has taken many forms over the years, primarily moving from domination and using wild animals as symbols of power and wealth in ancient and medieval menageries to scientific curiosity in the 19th-century zoos and then appreciation, respect and the desire to conserve in modern zoos.

Zoos have faced criticism from **animal rights** campaigners who fundamentally believe that animals should not be kept in captivity. They have also been criticized by animal welfare campaigners, who do not object to animals in captivity as long as they enjoy good welfare standards, which they claim many zoo animals do not. Continuously improving husbandry and

veterinary techniques in zoos now means that most zoo animals enjoy very high standards of physical **health** and welfare, and often live longer and breed more successfully than their wild counterparts.

Most concern for zoo animal welfare now centres on their psychological well-being and the inevitable lack of opportunity, which results from being in captivity, to perform a full range of natural behaviour. The absence of the need for such behaviour, such as escaping from predators, may be beneficial for welfare. But there is good evidence that the internal **motivation** to perform some types of behaviour is very strong, and the lack of opportunity to do so can lead to poor welfare and possibly the development of **stereotypies** or other **abnormal** behaviour. The occurrence of such behaviour is usually assumed to be an indicator of suboptimal welfare. The prevalence of these behaviours across zoos in general is hard to determine, but there is no doubt that it does occur and that vast improvements have been made since the peak of anti-zoo activity in the 1980s. In many zoos new enclosures are bigger, provide greater complexity for their occupants and are designed with a greater understanding of species-specific behaviour and needs. Many zoos also place a large emphasis on environmental

P.654

enrichment, which encompasses many techniques to increase zoo animals' opportunities to perform a wider range of natural behaviour.

Criticism of animal welfare standards during the latter part of the 20th century created the need for zoos to justify the keeping of wild animals in captivity. At the same time there was increasing concern about species **extinction** and the need for wildlife **conservation**, and a growing recognition within the zoo community of the role zoos could play. As a result, in recent years zoos have become much more than simply visitor attractions; they now participate in education, conservation and scientific research. These 'new' roles have become legal requirements in many parts of the world e.g. the EU (Council of the European Union, 1999), but progressive zoos have been performing them for some time. WAZA and various regional zoo associations around the world - e.g. Europe (EAZA), North America (AZA) and Africa (PAAZAB) - have long required their members to be active in conservation, education and research, as well as having high standards of animal welfare. WAZA published their first World Zoo and Aquarium Conservation Strategy (WZACS) in 1993 and completely updated it in 2005. This document outlines what zoos around the world can and should achieve within the broad goals of conservation, education and research and is applicable to all zoos, whether publicly or privately owned and operated on a not-for-profit or a commercial basis.

Zoos and conservation

Despite conservation now being the most widely recognized role of zoos among the public, it is the most recent goal to be widely adopted by zoos. It was initiated most notably by Gerald Durrell, who founded Jersey Zoo (Durrell Wildlife Conservation Society) in 1959. Durrell and other early pioneers realized that zoos could be modern arks, saving species from otherwise certain extinction by bringing them into captivity and **breeding** them in safety, with the long-term goal of releasing them back into the wild once conditions became suitable. They began the first inter-zoo exchanges of animals for breeding purposes and established studbooks to keep breeding records, the forerunners of today's **captive breeding programmes** (see Box Z.1).

Box Z.1. Captive breeding programmes.

It is unfeasible (and unpopular with visitors) for a single zoo to hold enough individuals of one species to avoid **inbreeding** and gene loss and to maintain a genetically healthy population. To ensure large enough populations to do this, several zoos must cooperate in regular animal exchanges and good records must be kept of animal transfers and breeding history. Captive breeding programmes were established to do this and usually operate within a region (e.g. Europe) and are coordinated by the regional zoo association (e.g. EAZA). The various associations have established Taxon Advisory Groups (TAGs) to oversee the programmes within taxon groups, e.g. Old World monkey. Initially, paper records were used to maintain studbooks but these have been replaced by the computer databases ARKS, SPARKS and, recently, ZIMS, developed by the International Species Inventory System (ISIS).

Most regions have a higher and lower level of genetic management for species. The higher level involves specific targets for maintenance of genetic variation (often 90% of the founder diversity for 200 years) and requires the coordinator to make annual recommendations for pairing-up of certain individuals for breeding. The lower level is less intensive and involves monitoring and recording of breeding only.

EAZA's first programmes began in 1985 for six species and, in 2006, there were 40 TAGs operating 163 EEPs (higher-level management) and 153 ESBs (lower-level management); in North America the AZA has 107 SSPs (higher level) and 315 PMPs (lower level).

In addition there are currently 182 international studbooks coordinated by WAZA, which operate globally across all regions.

Conservation has also been the most successful PR story for zoos in recent times, and the modern ark 'breeding and **reintroduction**' scenario is now well established in the public's mind. However, there is a danger that zoos may become a victim of this PR success if the public believes that every animal in a zoo is destined for reintroduction to the wild. This is clearly not the case, and the public may be very disappointed to discover this. Most captive breeding programmes are not directly linked to reintroductions; rather, they are regarded as 'safety nets', managed with the aim of maintaining self-sufficient, genetically healthy captive populations in case the worst-case scenario happens in the wild. One criticism often made against the value of zoos for conservation is that many zoos hold large numbers of non-endangered species that take up much of the available **space**; another concerns the staff and effort required to run breeding programmes. Although this is true, zoos argue that while planning their collections they need to balance conservation needs with the ability to attract the paying public, or they cannot exist at all. In addition, many species that are not endangered today may soon become so and it is impossible to predict which species those will be.

There have been some very notable reintroduction successes, and zoos have been responsible for saving an increasing number of species from extinction and re-establishing them in the wild, e.g. Bali starling, scimitarhorned oryx and black-footed ferret. Zoos have been particularly successful when breeding and releasing native species; for instance, the hazel dormouse and British field cricket in the UK. However, considering the number of **endangered species** and the number of species held by zoos worldwide, these successes have been relatively few. It is argued by many anti-zoo campaigners that the cost of reintroducing zoo-bred animals to the wild in terms of money, time and animal welfare is not worth it and that the effort and money would be better spent protecting natural habitats. They also go so far as to argue that *ex situ* conservation (i.e. captive breeding) is detrimental as it reduces effort and finances

P.655

directed to *in situ* conservation efforts. However, there is little evidence that the money raised by and for zoos would find its way into *in situ* conservation schemes if zoos did not exist.

It is recognized within WZACS (WAZA, 2005) that simply participating in captive breeding programmes is not enough, and that zoos need to contribute more to *in situ* conservation. This can be done in several ways, including simply donating money or through cooperation and sharing of technology and expertise. Many zoo associations such as EAZA run annual fund-raising campaigns for field conservation that enable all zoos to contribute in a meaningful way without the need for any additional staff expertise. Many larger zoo organizations such as the Wildlife Conservation Society (New York zoos) have their own extensive programmes of field conservation projects.

Zoos, education and scientific study

Education of the general public and scientific investigation were both recognized as being roles of zoos by the Ancient Greeks, who were also the first known to charge entrance fees (c.500 BC). Although some of the early modern zoos were founded on scientific principles by learned societies (see below), public education was not generally accepted as an important function in modern zoos until comparatively recently. Paignton Zoo (Devon, UK), founded by Herbert Whitley in 1923, was an early pioneer of modern zoo education. Whitley was so determined that his zoo was a place of education and not entertainment that he twice closed its gates (in 1924 and 1937) rather than pay entertainment tax on ticket sales.

Zoos can be used as educational facilities for an enormously diverse range of subjects, including art, tourism and media studies, but their main strength is obviously zoology and related biological disciplines, and their emphasis must now be **ecology**, the environment and conservation education. Most zoos have formal education programmes that deliver a range of specialist courses to various student groups, from pre-school to university level. However, informal education of general visitors is also considered to be extremely important and has been the main driving force behind the trend towards holistic, immersion exhibits in zoos. According to this principle, every detail of the zoo, from animal enclosures to retail outlets and rubbish bins, should be designed to create the impression that visitors are in the animals' natural environment. In addition to the architecture, vegetation and visual imagery, zoos use physical props, artificial weather conditions, sounds and even smells to convince visitors that they are in a tropical rainforest or a desert or a mangrove swamp. It is believed that by doing this visitors gain a better appreciation of the animals together with their environment, and that this ultimately leads to greater concern for them and their conservation.

The impact of zoos' conservation education efforts on their 6 billion visitors worldwide each year is almost impossible to evaluate, but it is claimed by many zoos to be their most important function. Indeed, it seems intuitive that seeing actual, living wild animals close up will have an important and positive influence on many people. Zoos are making increasing

numbers of attempts to evaluate their educational impact, but to date the body of hard evidence to support their claim that it is a significant factor in influencing people for wildlife conservation is still small.

Although some ancient zoos, such as Emperor Wen Wang's Garden of Intelligence (China, c.1000 BC), were established for the advancement of biological knowledge, most were simply ménageries kept for human amusement and to demonstrate power and wealth. The first 'modern' zoo to be founded on scientific lines was at Versailles, France, in 1664 and became the Menagerie des Jardin de Plantes (Paris) in 1793, 'a place of science for knowledge and progress'. The Zoological Society of London established London Zoo along the same principles in 1828, at which time it was only open to fellows of the society for scientific study. It did not open to the general public until 1847. Major cities around the world created zoos along similar principles shortly afterwards, e.g. New York (Central Park Zoo) and Melbourne, Australia, both in 1860.

During this heyday of European empire building and increased global exploration, these great city zoos had a seemingly never-ending supply of new species to be inspected, described and classified, and much zoo science was simply that. During the 20th century, as fewer and fewer large vertebrates remained to be documented, science within zoos became less important. Zoology was branching towards either the laboratory, where precisely controlled experimental manipulations could be performed, or the field, where results would not be affected by 'unnatural' surroundings. However, a number of prominent researchers, such as Frans de Waal, still appreciated modern zoos as useful facilities for some types of research. Good zoo exhibits with reasonably natural environments and social groupings of animals, excellent animal records and well-informed, cooperative staff can provide excellent halfway houses between the two extremes of **laboratory study** (totally unnatural but highly controlled) and field (totally natural but completely uncontrolled). This realization is growing, and progressive zoos are increasingly developing strong links with academic institutions, such as universities and natural history museums, in order to make good scientific use of their distinctive collections.

Zoo animal

A zoo animal is any individual animal that lives in a zoo. Zoos are usually defined by the presence of captive, non-domestic

animals so most zoo animals are non-domesticated species. However, many zoos also keep domestic species, usually to provide opportunities for visitors to touch animals, and these are also zoo animals (**see: Domestication**).

Zoonotic disease

A zoonotic disease is one that passes from animals to humans and vice versa (although the latter may also be referred to as an anthroponosis). Bacteria such as *Salmonella* spp. and *Campylobacter* spp. may infect other animals directly through the feed or food. Transfer may also occur from humans to their companion animals, and from farmed animals to humans (e.g. from cows' milk, rabies through bites from **cats** and **dogs**).

Zoophilia

Zoophilia is a term derived from the Greek *zôon* (animal) and *philia* (friendship or love) that refers generally to the state of having an affinity for animals. The more common form of this affinity refers to sexual attraction by a human to a non-human animal.

Zygote

A zygote is the single diploid cell resulting from fusion of two haploid gametes in the process of fertilization. Following the initiation of cleavage to produce a two-cell structure, the zygote is generally thereafter termed an **embryo**.
